Management of Muscle-Invasive and Metastatic Bladder Cancer

Thomas J. Guzzo MD, MPH, John P. Christodouleas MD, MPH, David J. Vaughn MD

Clinical Presentation, Diagnosis, and Evaluation

Bladder cancer has the fifth highest incidence of all malignancies in the United States, with an estimated 81,190 new cases and 17,240 deaths in 2018 (Siegel et al., 2018). Twenty percent to 30% of patients will present with muscle-invasive bladder cancer at the time of initial presentation. Despite aggressive therapy, a significant proportion of patients ultimately will experience recurrence and will die of their disease. Clinical understaging is not uncommon at the time of initial diagnosis with muscle-invasive disease, and therefore a multimodal therapeutic approach is often necessary to improve survival. A multidisciplinary approach is paramount to integrate appropriate therapy to individual patients, including surgery, systemic chemotherapy, and radiation therapy. This chapter reviews the evaluation and treatment of patients with muscle-invasive and metastatic bladder cancer.

Natural History

The majority of patients present with muscle-invasive disease at the time of initial presentation. A smaller subset (approximately 20%) will progress to muscle-invasive disease after an initial diagnosis of non–muscle-invasive bladder cancer. Muscle-invasive bladder cancer is a highly lethal entity and if left untreated will result in mortality within 2 years of diagnosis in 85% of cases (Prout and Marshall, 1956). Additionally, some studies have shown poorer outcomes for patients who progress from non–muscle-invasive disease; however, this may be related to understaging of presumed noninvasive disease or significant progression while undergoing conservative therapy rather than a biologic difference in disease aggressiveness (Guzzo et al., 2009). Bladder cancer death after appropriate local therapy is typically the result of systemic disease; the majority of deaths occur within 2 years of initial treatment. Non–local-regional relapses are reflective of the presence of micrometastatic disease at the time of diagnosis and treatment, and this continues to hamper long-term survival rates for patients with muscle-invasive disease. The significant risk for micrometastatic disease and our current inability to stage and to identify accurately patients with non–organ-confined disease before definitive local therapy continue to hamper pretreatment decisions and argue for a multidisciplinary treatment approach.

Histology

The majority of primary bladder cancers are urothelial carcinomas, representing more than 90% of all bladder tumors. Although squamous cell carcinoma comprises only approximately 5% of all bladder cancers in the Western world, it is more common in parts of the Middle East and Africa secondary to endemic infection with schistosomal parasites, and it accounts for a significant percentage of bladder cancer histology in these regions (el-Mekresh et al., 2009). Of note, the proportion of pure squamous cell bladder cancers in this part of the world does appear to be decreasing likely related to effective anti-bilharzia medications and decreasing prevalence of smoking (Antoni et al., 2017). Squamous cell carcinoma histology in Western countries is more commonly associated with chronic urinary tract inflammation including patients with chronic indwelling catheters. Even rarer, adenocarcinomas represent roughly 2% of bladder cancers and can originate from either the urothelium or the urachus. Patients with bladder exstrophy are classically at an increased risk for bladder adenocarcinoma. Before definitive treatment, it is important to rule out other more common sites of adenocarcinoma such as breast and colorectal sources. Standard treatment regardless of histologic subtype is radical cystectomy; however, timing of neoadjuvant chemotherapy and/or radiation therapy can vary by histologic subtype (Willis et al., 2013). Pure neuroendocrine variants of bladder cancer are relatively rare but highly aggressive, and they typically present at high pathologic stages or with metastatic disease (Mazzucchelli et al., 2009). Neuroendocrine features can also be seen with other histologic variants. Standard treatment for neuroendocrine bladder tumors includes neoadjuvant chemotherapy and radical cystectomy (Siefker-Radtke et al., 2004). Neuroendocrine tumors can be associated with paraneoplastic syndromes including ectopic adrenocorticotropic hormone production, hypercalcemia, and hypophosphatemia. Carcinoid tumors, a type of neuroendocrine tumor, can also originate in the bladder. Large cell neuroendocrine tumors have also been reported and have a similar disease biology to that of small cell tumors (Akamatsu et al., 2008). Other rare histologic entities include rhabdomyosarcoma, leiomyosarcoma, and primary lymphoma.

Variant histologies of urothelial carcinoma also exist, including micropapillary, sarcomatoid, squamous, and glandular differentiation. Micropapillary tumors are aggressive and resemble papillary serous carcinoma of the ovary. There are conflicting reports regarding the responsiveness of micropapillary disease to neoadjuvant chemotherapy (Ghoneim et al., 2011; Kamat et al., 2007; Meeks et al., 2013). There is scant evidence to support treatment guidelines for many variant urothelial histologies; however, many of these subtypes are aggressive, and early definitive therapy should be considered. It is important to recognize variant histology to avoid diagnostic misinterpretations that could delay definitive care.

Clinical Staging

Clinical staging for bladder cancer is the assessment of disease extent before radical cystectomy, whereas pathologic stage is determined by microscopic analysis of radical cystectomy and pelvic lymphadenectomy specimens. Clinical staging for bladder cancer is determined by pathologic analysis of the depth of the invasion of the tumor on the transurethral resection (TUR) specimen, bimanual examination of the patient under anesthesia, liver function tests, chest radiography, and contrast-enhanced cross-sectional imaging of the abdomen and pelvis with upper tract imaging. Clinical and pathologic T and N staging discordance is very common. Contemporary cystectomy series demonstrate pathologic upstaging and downstaging rates to be as high as 50% and 25%, respectively, for patients with clinical T2 stage tumors (Table 137.1) (Svatek et al., 2011).

TABLE 137.1

Incidence of Pathologic Pelvic Node Metastasis (%) at Radical Cystectomy in Selected Contemporary Series (2000–2012)

	NO. OF PATIENTS	P1	P2A	P2	P2B	P3A	P3	P3B	P4A	P4	P4B

TUR is the gold standard method for establishing the diagnosis of muscle-invasive bladder cancer. In addition to pathologic staging, TUR also can provide valuable information on histologic variants that may direct therapeutic decision making. Although data are limited, a complete resection of macroscopic tumor is advisable when it is safe and feasible. Complete resection decreases local tumor burden and may optimize the response to neoadjuvant chemotherapy, or for patients undergoing chemoradiotherapy it may improve the likelihood of successful bladder preservation. Additionally, prospective randomized neoadjuvant chemotherapy trials have clearly demonstrated a significant survival benefit in patients who are pT0 at the time of radical cystectomy. This survival benefit (pT0 status) occurred regardless of whether neoadjuvant chemotherapy was administered, suggesting a potential benefit of aggressive TUR (Grossman et al., 2003b; Lavery et al., 2014). The status of the bladder neck in women and the prostatic urethra in men should also be carefully evaluated at the time of initial resection, as it can affect clinical decision making with regard to neoadjuvant chemotherapy (prostatic stromal invasion), surgical management of the urethra, choice of urinary diversion at the time of radical cystectomy, and clinical target volumes in radiotherapy. Biopsies of the prostatic urethra may provide useful information in advance of radical cystectomy (Lerner and Shen, 2008). Using a resectoscope, a full loop of tissue is taken from the midprostate (or bladder neck in shorter prostates) to the mid- to distal verumontanum and 5 and 7 o'clock adjacent to the verumontanum. This is the site of the highest concentration of prostatic ducts and the area where carcinoma in situ (CIS) is most likely to be found (Sakamoto et al., 1993). The full-thickness prostatic resection allows the pathologist to evaluate the interface between the urethral mucosa, prostatic ducts, and stroma, which allows for accurate staging of the prostatic urethra (Wood et al., 1989). Negative prostatic urethral biopsies are associated with negative apical urethral margins, and it has been suggested that they can replace the need for intraoperative frozen section at the time of radical cystectomy; however, it remains this author's practice to send a full-thickness intraoperative frozen section margin from the urethra in patients who desire a neobladder (Lerner and Shen, 2008). In women, bladder neck biopsy is an accurate surrogate for urethral biopsy when orthotopic urinary diversion is under consideration.

Bimanual examination under anesthesia remains an important aspect of primary tumor assessment. The examination is performed typically by placing the dominant hand on the suprapubic region and one or two fingers from the nondominant hand in the rectum (males) or vagina. Bimanual examination can be performed at the time of initial tumor resection and should be done before and after resection. The bimanual examination should be performed with the bladder drained and without a Foley catheter in place to maximize palpation of the bladder. Findings described originally by Marshall are T2a: nonpalpable; T2b: induration but no three-dimensional mass; T3a: three-dimensional mass that is mobile; T4a: invading adjacent structures such as the prostate, vagina, or rectum; T4b: fixed to pelvic sidewall and not mobile (Marshall, 1952). Bimanual examination is not 100% accurate in predicting final tumor pathology, with an 11% clinical overstaging and a 31% clinical understaging rate reported (Ploeg et al., 2012).

Cross-sectional imaging plays an important adjuvant role to TUR and physical examination in the assessment and staging of the primary bladder tumor in patients with muscle-invasive disease. Abdominal and pelvic cross-sectional imaging are recommended by the National Comprehensive Cancer Network (NCCN) when muscle-invasive disease is suspected before TUR (NCCN guidelines Version 1, 2014). Studies vary widely on the overall sensitivity and specificity of computed tomography (CT) imaging with regard to final pathologic tumor stage at the time of radical cystectomy. Studies using multidetector CT scanners have reported the most favorable results, with sensitivities ranging from 89% to 91% and specificities of 92% to 95% for local staging (Kim et al., 2004; Koplay et al., 2010). The timing of imaging relative to TUR is also important to note. Although it is optimal to obtain cross-sectional imaging before TUR, if imaging is obtained subsequently, it should be delayed approximately 7 days postprocedure to minimize inflammatory artifact, which can be mistaken for T3 disease (Kim et al., 2004). A high suspicion for extravesical disease is warranted when hydronephrosis is noted on cross-sectional imaging. The presence of hydronephrosis on staging CT is associated with an increased risk for extravesical disease (27.8% vs. 17.3%) at the time of cystectomy (Bartsch et al., 2007; Canter et al., 2008). The reported sensitivity and specificity of CT in detecting nodal metastasis ranges from 31% to 50% and 68% to 100%, respectively (Baltaci et al., 2008; Lodde et al., 2010; Picchio et al., 2006).

Magnetic resonance imaging (MRI) is generally considered to be more accurate than CT in detecting local tumor stage; however, reports vary in the literature. Rajesh et al. (2011) reported on 100 consecutive patients who underwent a 1.5-T MRI with gadolinium. The authors reported that the sensitivity and specificity of MRI in differentiating between organ-confined and non–organ-confined disease was 90.5% and 60%, respectively. Other studies have reported staging sensitivity ranging from 68% to 80% and specificity of 90% to 93%. Advancements in MRI technology including 3.0 T magnets, dynamic contrast enhancement, and diffusing weighted imaging have demonstrated improved ability to locally differentiate T-staging of tumors compared with that of CT; however, an inability to improve on the detection of occult lymph node metastasis remains a limitation (Rose and Lotan, 2018; Panebianco et al., 2016). Additionally, MRI has been reported as useful in predicting tumor grade and tumor chemosensitivity (Tuncbilek et al., 2009; Yoshida et al., 2012).

The usefulness of positron emission tomography and CT (PET/CT) in local staging of bladder cancer is limited as a result of the excretion of standard PET (^{18}F-fluorodeoxyglucose) into the urine. Although PET/CT has not proven of superior benefit to that of CT alone for local staging, some studies have demonstrated its superiority with regard to nodal staging. The reported sensitivity and specificity of PET/CT in detecting nodal metastasis ranges from 57% to 81% and 88% to 100%, respectively (Apolo et al., 2010; Drieskens et al., 2005; Kibel et al., 2009; Lodde et al., 2010). Although conventional CT will detect the majority of lymph node metastasis found with PET/CT imaging, Kibel et al. (2009) reported a modest improvement in the detection of nodal metastasis with PET/CT imaging. Novel radiotracers have also been investigated in an attempt to mitigate the limitations of traditional FDG studies. Radiotracers including ^{11}C-choline, ^{11}C-acetate, and ^{11}C-methionine have all been investigated typically with limited improvement over conventional techniques (Rose and Lotan, 2018).

Pathologic Staging

The American Joint Committee on Cancer (AJCC) tumor, node, metastases (TNM) system is the most commonly used method for staging bladder cancer (Table 137.2) and can be used for staging patients clinically and pathologically. Staging follows a stepwise fashion based on depth of tumor penetration. As with other tumors, N and M stages refer to the presence of regional nodal and distant metastasis, respectively. The 8th edition of the AJCC does have some changes worth noting (Paner et al., 2018). Involvement of perivesical lymph nodes are now included in the regional nodal staging. Lymph node metastasis beyond the common iliac vessels is now classified as M1a, given its improved survival relative to patients with non–lymph node metastasis (Galsky et al., 2013). The prognostic value of T2 and T3 substaging has been widely reported. A multicenter series of 565 radical cystectomy patients with pT2, node-negative disease demonstrated improved recurrence-free (73.2% vs. 58.7%) and cancer-specific survival (78.0% vs. 65.1%) for pT2a and pT2b disease, validating this subgrouping (Tilki et al., 2010a). The prognostic usefulness of the pT3 subgrouping was also reported in the same cohort of radical cystectomy patients. Of the 356 pT3N0 patients, pT3b substaging was associated with poorer recurrence-free (60.7% vs. 47.9%) and cancer-specific survival (64.4% vs. 55.0%) at 5 years (Tilki et al., 2010b). The T4a prostate designation requires established stromal invasion, which can occur via the urethra or as a direct extension via the bladder neck or posteriorly into the seminal vesicles or periprostatic ducts. CIS in the prostatic urethra or ducts does not represent upstaging because outcome is determined by the primary bladder cancer stage (Esrig et al., 1996; Pagano et al., 1996). Pathologically, organ-confined bladder cancer is considered to be pT2bN0M0 or less at the time of cystectomy (Soloway et al., 2012).

TABLE 137.2

Tumor Node Metastasis Staging System for Bladder Cancer

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ: “flat tumor”
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis propria
pT2a	Tumor invades superficial muscularis propria (inner half)
pT2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus,

	vagina, pelvic wall, abdominal wall		
T4a	Tumor invades prostatic stroma, uterus, vagina		
T4b	Tumor invades pelvic wall, abdominal wall		
REGIONAL LYMPH NODES (N)[a]			
Nx	Lymph nodes cannot be assessed		
N0	No lymph node metastasis		
N1	Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, perivesical, or presacral lymph node)		
N2	Multiple regional lymph node metastasis in the true pelvic (hypogastric, obturator, external iliac, or presacral lymph node metastasis)		
N3	Lymph node metastasis to the common iliac lymph nodes		
DISTANT METASTASIS (M)			
M0	No distant metastasis		
M1	Distant metastasis		
ANATOMIC STAGE/PROGNOSTIC GROUPS			
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a	N0	M0
	T2b	N0	M0
Stage III	T3a	N0	M0
	T3b	N0	M0
	T4a	N0	M0
Stage IV	T4b	N0	M0
	Any T	N1-3	M0
	Any T	Any N	M1

[a] Regional lymph nodes include both primary and secondary drainage regions. All other nodes above the aortic bifurcation are considered distant lymph nodes.

Note: cTNM is the clinical classification, and pTNM is the pathologic classification.

Radical Cystectomy and Pelvic Lymph Node Dissection for Muscle-Invasive Bladder Cancer

For patients with clinical T2–T4a, N0, M0 disease, radical cystectomy and bilateral pelvic lymph node dissection remains the gold standard therapy by which all other treatment modalities should be compared. Although utilization varies with age and comorbidities, approximately 80% of muscle-invasive patients who undergo definitive management have a radical cystectomy (Bekelman et al., 2013). Radical cystectomy provides excellent local control, with pelvic recurrence rates as low as 4% in patients with node-negative disease (Morris et al., 2009). Randomized trial data have demonstrated superior outcomes with neoadjuvant systemic chemotherapy, which will be discussed later in this chapter.

Time from initial diagnosis of muscle invasion to cystectomy likely affects oncologic outcomes, particularly if there is a delay of greater than 12 weeks. Sanchez-Ortiz et al. (2003) initially published this observation in their cohort of 290 cystectomy patients noting a higher proportion of extravesical tumors, nodal metastasis, and poorer survival in patients in which cystectomy was delayed more than 12 weeks. Since this observation was published, multiple studies have demonstrated similar results (Chang et al., 2003; Gore et al., 2009; Lee et al., 2006b). Lee et al. (2006b) reported poorer disease-specific survival (DSS) and overall survival (OS) rates for patients with muscle-invasive disease who underwent radical cystectomy more than 3 months after initial diagnosis. Administrative data sets have also provided similar findings. Of 441 patients who underwent radical cystectomy from 1992 to 2001 in the Surveillance, Epidemiology, and End Results (SEER) database, a delay in surgery of more than 12 weeks and 24 weeks resulted in a twofold increase in disease-specific and overall mortality compared with more timely surgical intervention (Gore et al., 2009). Similar results have been noted in other radical cystectomy cohorts (Ayres et al., 2008; Fahmy et al., 2008; Kulkarni et al., 2009). Although it is difficult to say with certainty, based on retrospective surgical cohorts, exactly how expeditiously surgery should be performed, a significant delay does appear to be detrimental to oncologic outcomes.

In men, radical cystectomy includes excision of the surrounding perivesical soft tissue, prostate, and seminal vesicles, and, in women, it includes the ovaries, uterus with cervix, and anterior vagina. Since the mid-2000s, greater emphasis has been placed on urinary and sexual quality of life following cystectomy. This has led to a greater interest in organ preservation in both men and women. In men, preservation of the neurovascular bundles, some or all of the prostate, and the seminal vesicles have been reported in an attempt to improve postoperative quality of life. The majority of reports are limited to small retrospective cohorts and must be analyzed within the context of such limitations. It is also important for the surgeon to weigh the oncologic risk for organ preservation relative to that of cancer recurrence. For instance, prostate cancer can be present in upward of 23% to 54% of radical cystoprostatectomy specimens, with up to one-third having clinically significant disease (Abdelhady et al., 2007; Pettus et al., 2008). Additionally, the significant incidence of urothelial carcinoma involving the prostate (17% to 75%) noted on complete radical cystoprostatectomy specimens is an obvious oncologic limitation with this technique (Arce et al., 2011; Ayyathurai et al., 2007; Pettus et al., 2008; Revelo et al., 2008; Richards et al., 2010; Tabibi et al., 2011). If prostatic preservation is considered, transurethral sampling of the prostatic urethra and bladder neck is advisable to maximize appropriate patient selection. Other reported preoperative features associated with prostatic urethral involvement include the presence of tumor at the bladder neck (Abdelsalam et al., 2011; Arce et al., 2011; Pettus et al., 2008; Richards et al., 2010), tumor multifocality (Kefer and Campbell, 2008; Nixon et al., 2002), and the presence of CIS (Arce et al., 2011; Kefer and Campbell, 2008; Richards et al., 2010). Functional outcomes after prostate preservation tend to be directly associated with the amount of tissue spared at the time of surgery. Davila et al. (2007) reported on a small number of patients undergoing either apical ($N = 15$) or total prostate-sparing cystectomy ($N = 6$). Using the erectile function domain score of the International Index of Erectile Function (IIEF) questionnaire, the authors reported mild erectile dysfunction in the apical-sparing group. Also using an apical-sparing technique, Wunderlich et al. (2006) reported a 94% daytime and nighttime continence rate, with 87% of patients achieving baseline erectile function following surgery. Posterior sparing (posterior prostate and seminal vesicles) was also reported by several authors with limited numbers of patients. Using this technique, excellent outcomes with regard to continence and erectile function have been reported (Girgin et al., 2006; Spitz et al., 1999). Finally, total prostate sparing has also been described in several series of patients. Nieuwenhuijzen et al. (2008) reported outcomes of 41 patients who underwent total prostate sparing at the time of radical cystectomy, and they noted 95% and 74% daytime and nighttime continence rates, respectively. However, 12 patients did require long-term clean intermittent catheterization because of an inability to empty volitionally. Erectile function was maintained in 78% of patients who were functioning preoperatively. Although organ preservation has the potential to improve overall quality of life, radical cystoprostatectomy remains the gold standard.

Preservation of the uterus, ovaries, and vagina has also been explored in women at the time of radical cystectomy. Although an anterior exenteration has classically been advocated in women at the time of radical cystectomy, urothelial carcinoma rarely involves the gynecologic organs, with an overall incidence of approximately 5% of cases (Chang et al., 2002). Unless there is tumor involvement of the bladder neck, a complete urethrectomy can be omitted at the time of cystectomy, allowing for orthotopic bladder substitution in women. Additionally, carefully selected patients can also forgo removal of the uterus and anterior vagina, which potentially allows for better anatomic support for a neobladder and preserves the autonomous nerves.

Bilateral Pelvic Lymph Node Dissection

A meticulous pelvic lymph node dissection is an essential component of radical cystectomy. It is well established that approximately 25% of patients will have pathologic lymph node metastases at the time of cystectomy (Lerner et al., 1993), and lymph node status is the most powerful surrogate for long-term recurrence-free and OS following radical cystectomy (Poulsen et al., 1998; Stein et al., 2001). Skinner (1982) was first to report the value of a meticulous pelvic lymph node dissection, demonstrating better local control rates, potential for cure, and acceptable morbidity in patients undergoing radical cystectomy. Since that initial report, multiple surgical series have demonstrated the profound impact of nodal involvement at the time of radical cystectomy, with approximately 70% to 80% of patients with lymph node metastasis ultimately experiencing disease recurrence in contrast with approximately 30% of patients with a negative pelvic lymph node dissection (Shariat et al., 2006b; Stamatakis et al., 2012). The extent of lymph node dissection at the time of cystectomy has been shown as an independent predictor of survival and local recurrence, even when chemotherapy status and other pathologic factors are controlled (Herr et al., 2004). Whereas the importance of a lymph node dissection seems undebatable, what actually constitutes an adequate lymph node dissection and its exact therapeutic benefit remains less clear.

Anatomic Extent of Pelvic Lymph Node Dissection and Landing Zones

The primary lymphatic drainage site for bladder cancer includes the internal iliac, external iliac, obturator, and presacral lymph nodes. Secondary drainage sites include higher echelon nodes, including the common iliac, para-aortic, interaortocaval, and paracaval lymph nodes (Abol-Enein et al., 2004; Leissner et al., 2004; Vazina et al., 2004). Although multiple studies have demonstrated that an extended pelvic lymph node dissection offers improved prognostic staging, the exact anatomic extent of dissection remains somewhat controversial. The cranial extent of an adequate lymph node dissection varies across cystectomy series ranging from the crossing of the ureter at the level of the common iliac vessels to as high as above the aortic bifurcation at the level of the inferior mesenteric artery (Abol-Enein et al., 2004; Leissner et al., 2004; Mills et al., 2001; Poulsen et al., 1998).

Multiple surgical series have evaluated the anatomic extent and distribution of nodal metastasis at the time of cystectomy. In Mansoura, Egypt, Abol-Enein et al. (2004) evaluated the extent and distribution of positive lymph nodes in 200 consecutive patients who underwent radical cystectomy at a single institution over a 4-year period. The anatomic extent of the lymph node dissection was the inferior mesenteric artery superiorly in all patients. Twenty-four percent of patients exhibited nodal disease, with a mean number of eight positive lymph nodes. In 22 patients, only a single lymph node was positive, of which 21 were located in the endopelvis. Metastasis outside of the true pelvis was only found in multinodal disease and was associated with involvement of the obturator and/or iliac nodes in all cases. The authors found no evidence of “skip” metastasis in patients with positive nodes. The authors suggested that the obturator and internal iliac nodes represent the sentinel lymphatic drainage areas and that if lymphadenectomy proved to be negative on frozen-section analysis at the time of surgery, a more superior dissection was not warranted. Similarly, the Memorial Sloan Kettering Cancer Center (MSKCC) group has reported on the anatomic extent and spread of lymph node metastasis (Bochner et al., 2004). The authors reported on 144 patients who underwent either a standard or extended pelvic lymph node dissection at the time of radical cystectomy. A standard pelvic lymph node dissection was defined superiorly by the iliac bifurcation and included the external iliac, hypogastric, and obturator lymph node packets. An extended dissection also included the nodal packets to the level of the aortic bifurcation to no more than 2 cm proximal to the bifurcation. The common iliac and presacral nodes were also included in the extended dissection template. As one would expect, the absolute number of positive nodes was significantly higher in the extended lymph node dissection group (22.5 vs. 8). However, there was no staging advantage noted in the extended lymph node group, with both dissections yielding the same percentage of patients with positive lymph nodes (21%). Four percent of patients presented with positive lymph nodes identified within the para-aortic packets, all of whom also showed positive lymph nodes in lower dissection packets. The authors did note four patients with micrometastatic disease to the common iliac vessels only, concluding that this area should be considered part of the standard lymph node dissection.

Although “skip” metastasis appears to be a relatively rare event in bladder cancer, it has been reported in the literature. A prospective multicenter study of 290 patients undergoing radical cystectomy with extended pelvic lymphadenectomy reported nodal metastasis in 27.9% of patients (Leissner et al., 2004). The authors reported lymph node metastasis based on three defined anatomic regions. Level 1 included lymph nodes below the common iliac bifurcation, level 2 included lymph nodes above the common iliac bifurcation but below the aortic bifurcation, and level 3 included lymph nodes to the level of the inferior mesenteric artery. Although no skip lesions were noted above the level of the aortic bifurcation, 6.9% of patients had nodal metastasis in level 2. Tarin et al. (2012) reported their lymph node dissection findings in 591 patients undergoing a radical cystectomy during a 10-year period, of which 19% exhibited positive nodes. The authors reported 6% of patients with skip lesions above the common iliac bifurcation, with no positive nodes in the true pelvis. Finally, Vazina et al. (2004) also reported one patient with lymph node metastases at or above the aortic bifurcation or common iliac region without nodal involvement of more distal sites in their series of 176 radical cystectomy patients.

The anatomic extent of the pelvic lymph node dissection has also been evaluated in multiple series with regard to oncologic outcome. Dhar et al. (2008) reported on two consecutive series of patients from the Cleveland Clinic and the University of Bern, totaling 658 patients who either underwent a limited or an extended pelvic lymph node dissection. The limited node dissection included the pelvic sidewall between the genitofemoral and obturator nerves, and the bifurcation of the iliac vessels to the circumflex iliac vein. The extended dissection extended cephalad to the crossing of the ureters with the common iliac arteries and removal of all tissue along the lateral and medial portion of the internal iliac vessels. The overall proportion of node-positive patients in the extended versus limited cohorts was 26% and 13%, respectively. The 5-year recurrence-free survival of patients with node-positive disease was 7% for limited node dissection and 35% for extended node dissection. The 5-year recurrence-free survival for pT2pN0 cases was 67% and 77% for limited and extended dissections, respectively, and 23% and 57% for pT3N0 cases, respectively. The 5-year recurrence-free survival for pT2pN0-2 cases was 63% and 71%, respectively, for limited and extended lymph node dissections and 19% and 49%, respectively, for pT3pN0-2 patients. This study, in a large cohort of patients, confirms the value of an extended pelvic lymph node dissection with regard to staging accuracy and prognosis.

Based on anatomic mapping studies, it is recommended that a standard pelvic lymph node dissection at the time of radical cystectomy include the lymph node packets from the external iliac lymph vessels up to the level of the common iliac bifurcation cephalad and the genitofemoral nerve laterally to the ureter medially. An extended template dissection should include the tissue extending above the common iliac bifurcation to the aortic bifurcation and presacral region. Finally, with a superextended lymph node dissection, the tissue up to the level of the inferior mesenteric artery should be included (Sanli et al., 2017). The exact anatomic extent of dissection remains debatable; however, clinical recent and ongoing clinical trials will ultimately answer this question. The German Urologic Oncology Group (AUO) prospective, randomized trial comparing limited dissection (obturator, internal and external iliac nodes) with extended dissection (limited plus deep obturator, presacral, paracaval, interaortocaval, and paraaortal nodes) did not demonstrate a 5-year difference in recurrence-free or cancer-specific survival between these two groups; however, the extended arm did demonstrate nonsignificant absolute improvement in these categories (69.3% vs. 62% and 77.5% vs. 66.2%, respectively) (Gschwend et al., 2016). We also await the results of the Southwest Oncology Group (SWOG) S1011 prospective, randomized trial comparing survival in cystectomy patients undergoing extended or standard pelvic lymph node dissection (NCT01224665).

Number of Lymph Nodes Identified at the Time of Cystectomy

Multiple retrospective surgical series have attempted to quantify the minimum number of lymph nodes that constitutes an adequate pelvic lymph node dissection (Bochner et al., 2001; Herr, 2003; Leissner et al., 2000; Stein et al., 2003). Although controversy remains regarding the actual number of nodes that constitutes an adequate dissection, the absolute number of nodes removed has been shown to provide important prognostic information and staging accuracy both in node-positive and node-negative patients.

As one would expect, increasing nodal yield at the time of pelvic lymph node dissection improves the sensitivity of detecting nodal metastasis. Using a multi-institutional cohort, Capitanio et al. (2009) evaluated the probability of finding node-positive disease at the time of cystectomy based on the total number of lymph nodes removed. Of the 731 patients included in this study, 23.8% had positive nodes. Using receiver operating characteristic (ROC) curves, the authors predicted a 75% chance of identifying one or more lymph node metastases if 25 nodes were removed. This probability improved to 90% with 45 nodes and decreased to 50% if 15 to 25 nodes were removed, suggesting a 25-node minimum as a reasonable cutoff to adequately stage and detect lymph node metastasis (Fig. 137.1).

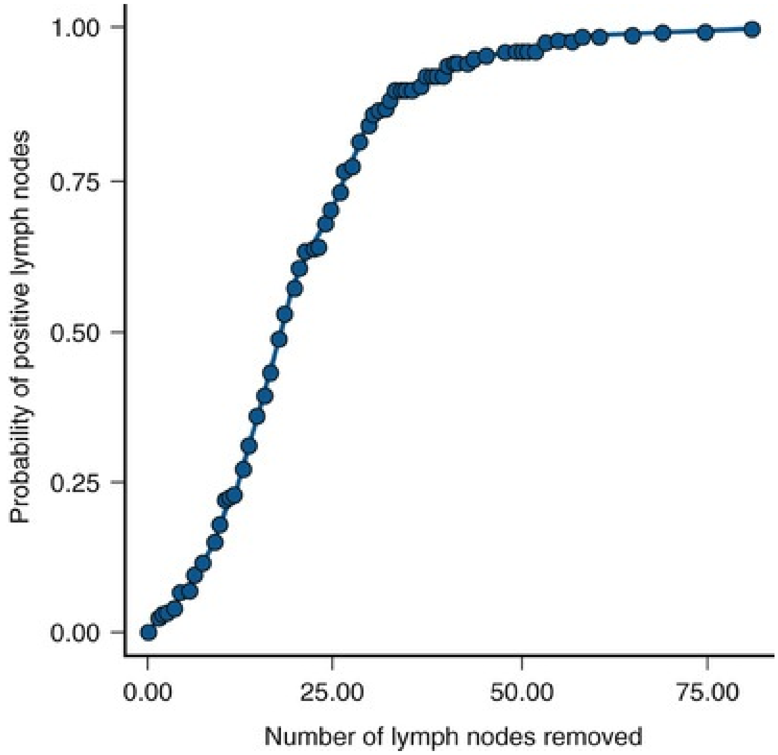

FIG. 137.1 A plot describing the relationship between the number of lymph nodes removed and the probability of detecting lymph node metastasis. (From Capitanio U, Suardi N, Shariat SF, et al. Assessing the minimum number of lymph nodes needed at radical cystectomy in patients with bladder cancer. *BJU Int* 103(10):1359–1362, 2009.)

In addition to staging, lymph node count has been reported to improve therapeutic efficacy; however, prospective data to substantiate such a benefit are currently lacking. Leissner et al. retrospectively analyzed outcomes in 447 cystectomy patients in Mainz, Germany (Leissner et al., 2000). Using a 16-node threshold, there were significant differences in cancer-specific and disease-free survival among patients with 16 or more lymph nodes removed compared with those who had fewer nodes removed. For their survival analysis, a 16-node threshold was used because the correlation between the total number of lymph nodes removed and the percentage of positive nodes was strongest at this count. There is no general consensus in the literature regarding the exact threshold of nodes at which a survival benefit can be predicted, with most studies reporting numbers in the 9 to 16 range (Herr, 2003; Herr et al., 2002; Hollenbeck et al., 2008; Konety et al., 2003; Leissner et al., 2000; May et al., 2011; Stein et al., 2003). Koppie et al. (2006) from the MSKCC group reported a study designed to determine if there is a minimum number of lymph nodes analyzed, above which there is no improvement in survival. The study included 1121 patients who underwent radical cystectomy during a 14-year period. The authors were unable to find a plateau in the dose-response curve with an increasing number of nodes up to 23; however, few patients had more than 24 nodes removed. Limitations of this study include the fact that 13% of patients had no nodes identified on the pathology report, and the percent of patients who underwent an extended node dissection was not reported. The number of lymph nodes identified has also been showed to be consistently associated with risk for pelvic failure, with 10 lymph nodes being the most common threshold in studies of locoregional failure endpoint (Christodouleas et al., 2014; Ku et al., 2014; Novotny et al., 2015).

Although the studies in the last two sections have demonstrated the prognostic and therapeutic value of a thorough pelvic lymph node dissection at the time of radical cystectomy, it must be remembered that they are all either retrospective or nonrandomized reports. There are inherent biases that need to be accounted for when considering the actual value and extent of a pelvic lymph node dissection when one considers it from a nonprospective, nonrandomized approach. Surgical and nonsurgical factors, including anatomic extent of the template and pathologic processing, including the number of packets submitted to pathology, can greatly influence nodal counts (Ather et al., 2008; Bochner et al., 2001; Fang et al., 2010; Kulkarni et al., 2008; Stein et al., 2007a). More definitive studies are currently underway to better address this issue, including randomized controlled trials, with the goal of determining the importance and extent of lymph node dissection at the time of radical cystectomy.

Lymph Node Density and Extracapsular Nodal Extension

Lymph node density refers to the percentage of positive nodes relative to the total number of nodes removed (Kassouf et al., 2008). Studies regarding the impact of lymph node density on prognosis have been mixed. Stein et al. (2003) first described the concept of lymph node density in bladder cancer. In their study of node-positive bladder cancer patients, they identified a lymph node density of 20% to carry prognostic value. Herr (2003) also demonstrated the 20% lymph node density value to confer prognostic value. In their study of 162 patients with node-positive bladder cancer who had a lymph node density of less than 20%, these patients experienced a significantly more favorable 5-year DSS following radical cystectomy. Similarly, Guzzo et al. (2010) reported the outcomes of 85 node-positive patients following radical cystectomy, and they found that lymph node density less than 20% predicted a more favorable response to adjuvant chemotherapy. Conversely, Tarin et al. (2012) could not demonstrate an association between lymph node density compared with that of lymph node status alone in 591 radical cystectomy patients who underwent extended lymphadenectomy. A similar study by Jensen et al. (2012) of 167 radical cystectomy patients echoed these findings. Ku et al. (2015) published a meta-analysis on available lymph node density studies. The authors reported on 14 publications that included more than 3300 patients and found that lymph node density was significantly associated with poorer DSS; however, significant heterogeneity did exist among studies. The current lymph node density studies reported in the literature are retrospective surgical series, and they report varying lymph node counts and templates of dissection, in turn limiting comparisons among studies.

Several small retrospective series have reported the potential prognostic significance of extranodal extension. Fajkovic et al. (2013) evaluated extranodal extension in 748 node-positive bladder cancer cases treated with cystectomy at several centers. A total of 375 (50%) presented with extranodal extension. Using a multivariable model, including pT stage, tumor grade, age, gender, lymphovascular invasion, surgical margin status, lymph node density, total lymph nodes, number of positive nodes, and adjuvant therapy, extranodal extension was significantly associated with both disease recurrence and cancer-specific mortality. Similarly, Seiler et al. (2011) reported an extranodal extension to be an independent predictor of OS and DSS in a smaller cohort ($N = 162$) of node-positive patients.

Intraoperative Decision Making

Grossly Positive Nodes and T4b Disease

For patients with clinically positive lymph nodes, the standard of care is cisplatin-based systemic chemotherapy. Patients who have a radiographic complete or partial response to systemic therapy are candidates for and should be evaluated for cystectomy. Those undergoing cystectomy have been noted to have a complete pathologic response typically in the 14% to 25% range (Meiger et al., 2014; Urakami et al., 2015; Zargar-Shoshtari et al., 2016). Patients who do achieve a complete response appear to have a significant survival advantage with 5-year cancer-specific survival rates of 63% (Meiger et al., 2014). Herr also reported that the overwhelming majority of patients who initially respond to chemotherapy but do not have surgery are destined to recur (Herr, 2001), and therefore consolidative cystectomy should be strongly considered in appropriate surgical candidates who respond to systemic therapy.

If adenopathy is encountered at the time of cystectomy, a frozen section should be taken to confirm metastasis, and an extended lymph node dissection and radical cystectomy should be completed when feasible. Cystectomy is not performed when lymph node metastases are unresectable because of bulk, when there is evidence of extensive periureteral disease, when the bladder is fixed to the pelvic sidewall, or when the tumor is invading the rectosigmoid colon. Not surprisingly, if radical cystectomy is aborted, patient prognosis is poor. The Johns Hopkins group published their outcomes of 35 patients who had an aborted cystectomy because of intraoperative findings of metastatic disease (Guzzo et al., 2008). Sixty percent of patients in the study cohort died from disease progression at a median time of 26 months. Similarly, Yafi et al. (2011) reported outcomes on 31 patients in which cystectomy was aborted for unresectable disease. The 2-year and 5-year OS in this cohort of patients was 41% and 0%, respectively.

Intraoperative Frozen Sections of the Ureter

The incidence of involvement of the distal ureter with tumor on final pathology at the time of radical cystectomy was 6% to 8% (Gakis et al., 2011; Sharma et al., 1970). There is no definitive recommendation for the precise length of the distal ureter that should be removed at the time of surgery. Final ureteral margin status has proven to be an independent predictor of upper tract recurrence following cystectomy (Tran et al., 2008; Volkmer et al., 2009). However, the overall incidence of upper tract recurrence following cystectomy is a relatively rare event ranging from 2% to 8% (Gakis et al., 2011; Giannarini et al., 2010; Schumacher et al., 2006; Tran et al., 2008). There are several risk factors for upper tract recurrence following cystectomy including bladder CIS, distal ureteral involvement with tumor, and high-grade pTa-T1 disease (Volkmer et al., 2009). Upper tract recurrences have been reported to occur most commonly between 2 and 4 years postcystectomy (Meissner et al., 2007; Sanderson et al., 2007; Wagner et al., 2008). Unfortunately, when upper tract recurrences do occur, they are often locally advanced and can be associated with poorer outcomes than de novo upper tract disease (Balaji et al., 1999; Sanderson et al., 2007; Sved et al., 2004). The risk for upper urinary tract recurrence appears to be a stable event with time (Tran et al., 2008).

The role of intraoperative frozen-section analysis of the ureters at the time of cystectomy remains somewhat controversial. Although it would seem intuitive that achieving a negative ureteral margin is necessary, the literature has not always demonstrated improved outcomes with this approach (Lee et al., 2006a; Osman et al., 2007; Schoenberg et al., 1996; Silver et al., 1997). Contemporary studies report frozen-section analysis of the distal ureteral margins to have a 74% to 75% sensitivity, a 98% to 99% specificity, and a positive predictive value of 98% (Gakis et al., 2011; Raj et al., 2006). Whether or not sequential resection for positive frozen ureteral margins confers an absolute benefit remains questionable. An analysis of 1397 cystectomy patients who underwent frozen-section analysis of the distal ureters demonstrated an initial positive margin rate of 12.7% (Tollefson et al., 2010). In those with initial positive margins, 83% were subsequently converted to a negative margin with further resection. Interestingly, those with an initial positive margin but negative final margin still were at higher risk for upper tract recurrence (hazard ratio [HR] = 4.88, 95% confidence interval [CI] 3.02 to 7.90, $P < .001$) compared with those with initial negative margins. This risk was intermediate to that of those with positive final margins (HR, 7.37, 95% CI 4.3 to 16.44, $P < .001$). These findings suggest that patients with ureteral disease at the time of cystectomy experience an increased risk for upper tract recurrence regardless of margin status, but this risk can be at least partially mitigated by achieving a negative margin. Most recently, Moschini et al. (2016) reported their experience with the utility of intraoperative ureteral margins in 1447 patients. In their series, 25% of patients had an intraoperative positive margin that was ultimately converted to a negative margin in 48% of cases. Ureteral margins that were not converted to negative intraoperatively were associated with poorer cancer-specific mortality, but only in patients with negative soft tissue margins and without nodal metastasis. The impact of ureteral skip lesions has also been reported. Investigators from the University of Texas MD Anderson Cancer Center evaluated 660 radical cystectomy patients who had both a distal frozen and final proximal ureteral margin (Hoang et al., 2014). Ureteric skip lesions (negative distal frozen, positive proximal permanent margin) were identified in 4.8% of patients with CIS, which is the most common skip lesion (55.9% of cases). Skip lesions were associated with lower median OS in patients with pT0 or pTa disease.

Given the findings outlined earlier, it appears logical to attempt to clear the distal ureter when feasible at the time of radical cystectomy. When frank tumor is encountered, it should be resected to a negative margin. When CIS only is encountered, maximal resection without compromising ureteral length for urinary diversion is advocated, as it is debatable whether a negative CIS margin reduces upper tract recurrence or is definitively associated with poorer outcome (Lee et al., 2006a; Raj et al., 2006). In patients who are at high risk for an upper tract recurrence, ureteropyeloscopy, when feasible, is the most sensitive means for detecting upper tract recurrences.

Prostatic Urothelial Carcinoma and Management of the Distal Urethra

The absolute risk for urethral recurrence following cystectomy ranges from 4% to 8% in men (Cho et al., 2009; Huguet et al., 2008; Nelles et al., 2008; Nieder et al., 2004; Stein et al., 2005; Varol et al., 2004). The majority of urethral recurrences are symptomatic, but in patients who are deemed at high risk for such events, periodic cytology can be useful for detection of recurrences (Clark et al., 2004; Huguet et al., 2008). Risk factors for urethral recurrence include non–muscle-invasive disease on final pathology and prostatic urethral involvement (Huguet et al., 2008; Stein et al., 2005). The extent of prostatic involvement is also predictive of urethral recurrence. Prostatic stromal invasion is associated with the highest risk (as high as 30%) compared with that of prostatic urethral CIS and ductal or acinar involvement (Hardeman and Soloway, 1990). Urethrectomy should be considered in men with diffuse CIS of the prostatic urethra or ducts or if there is prostatic stromal invasion. Preoperative evaluation of the prostatic urethra via biopsy can be performed to characterize further the risk for urethral recurrence and help dictate intraoperative management of the distal urethra and choice of urinary diversion. The sensitivity and specificity of transurethral prostatic urethral biopsy is moderate, with a relatively low positive predictive value compared with final cystoprostatectomy specimens (Donat et al., 2001). Given the modest value of preoperative urethral biopsy, some experts advocate for urethrectomy only in the setting of a positive apical urethral margin (Donat et al., 2001; Stein et al., 2005). Small low-grade papillary tumors of the urethra can be resected before cystectomy and the urethra retained if there is no other indication for urethrectomy. Of note, several retrospective surgical series have reported a decreased risk for urethral recurrence in patients with orthotopic urinary diversions (Hassan et al., 2004; Nieder et al., 2004; Stein et al., 2005). Whereas some have hypothesized that this decrease may be related to a protective effect of exposing the urethra to urine, it is more likely a result of selection bias.

Managing the Female Urethra

Before female orthotopic bladder substitution became more commonplace, complete removal of the female urethra at the time of radical cystectomy was routine. T4 tumors involving the urethra and/or vagina mandate complete urethrectomy, and these patients should not be offered urethral preservation. Concomitant involvement of the urethra in women with bladder cancer ranges from 2% to 12% (Stein et al., 2007b; Stenzl et al., 1995). Clinical features associated with an increased risk for distal urethral tumor involvement include primary tumor location at the bladder neck, vaginal involvement, or inguinal lymphadenopathy (Maralani et al., 1997; Stein et al., 1995, 1998). Although tumor presence at the bladder neck is significantly associated with urethral involvement, approximately 60% of patients with tumors in this location will not have a tumor in the urethra on final pathology; therefore controversy exists with regard to an absolute need for complete urethrectomy in this setting. Frozen-section analysis of the distal urethra has demonstrated high correlation with final urethral margin and should be performed in all women in which orthotopic bladder substitution is being considered (Akkad et al., 2006; Stein et al., 1998). Isolated urethral recurrence following orthotopic bladder substitution occurs in approximately 1% of cases (Ali-El-Dein et al., 2009; Stein et al., 2009).

Oncologic Outcomes Following Radical Cystectomy

Table 137.3 illustrates the reported oncologic outcomes of large surgical series. Pathologic tumor stage and presence of nodal metastasis are the strongest predictors of recurrence and survival following cystectomy (Frazier et al., 1993; Ghoneim et al., 2008; Hautmann et al., 2006; Madersbacher et al., 2003; Shariat et al., 2006b; Manoharan et al., 2009; Stein et al., 2001). Patients who are pT0 or who have residual noninvasive disease on final pathology have excellent outcomes with 5-year cancer-specific survival rates approaching 90% (Ghoneim et al., 2008; Stein et al., 2001). Patients with pT2 tumors have 5-year DSS rates ranging from 70% to 81%. Pathologic T2 substratification has been shown in multiple studies to confer prognostic value with regard to recurrence-free and DSS (Bastian et al., 2008; Ghoneim et al., 2008; Tilki et al., 2010a). The presence of non–organ-confined disease (>pT2) is a strong predictor of outcome. Pathologic T3 patients fare significantly poorer, with 5-year DSS rates ranging from 40% to 52%. The prognostic value of pT3 substaging has been debated in the literature. Two large multicenter surgical series have reported a prognostic discrimination between pT3a and pT3b, with node-negative patients reporting an improved recurrence-free and DSS advantage in pT3a patients (Sonpavde et al., 2011; Tilki et al., 2010b). However, pT3 substaging has not demonstrated improved stratification in node-positive patients (Quek et al., 2004). Lymph node status appears to be the single greatest predictor of survival. Node-positive disease confers a poor prognosis, with 5-year DSS rates ranging from 21% to 35%. However, long-term survival has been reported in patients with low-volume lymph node metastasis (Bruins et al., 2009; Dhar et al., 2008; Rink et al., 2013; Steven et al., 2007).

TABLE 137.3

Percentage of 5-Year Disease-Specific Survival (DSS) by Pathologic Stage After Radical Cystectomy With and Without Pelvic Lymph Node Metastasis: Selected Series Reporting DSS (2000–2012)

SELECTED SERIES	NO. OF PATIENTS	≤P1	P2A	P2	P2B	P3A	P3	P3B	P4A, B	N NEG	N+
Stein et al., 2001	1054	88		81		68		47	44	78	35
Madersbacher et al., 2003	507	76		74			52		36	—	33
Hautmann et al., 2006	788	90		72			43		28	75	21
Shariat et al., 2006b	888	81		72			44		28	80	35
Ghoneim et al., 2008	2720	82	75		53		40		29	62	27
Manoharan et al., 2009	432	81		70			44		16	72	29

Margin status is also an important predictor of recurrence and survival following radical cystectomy (Dotan et al., 2007; Novara et al., 2010). A multicenter, retrospective study of 4410 radical cystectomy patients reported an overall soft tissue positive margin rate of 6.3% (Novara et al., 2010). A positive soft tissue margin was associated with a significantly increased risk for disease recurrence (HR 1.52, $P < .001$) and cancer-specific mortality (HR 1.51, $P < .001$). Additional variables that were reported to possess prognostic value following radical cystectomy include the presence of lymphovascular invasion

(Herrmann et al., 2008; Lotan et al., 2005; Shariat et al., 2010), molecular markers (Shariat et al., 2014; Youssef et al., 2011), surgical expertise and hospital volume (Konety et al., 2005), body mass index (Bagrodia et al., 2009), and age (Hollenbeck et al., 2004; Nielsen et al., 2007). Despite aggressive surgical therapy, approximately 50% of cystectomy patients will ultimately die of disease. Recurrence of disease often occurs within the first 2 years after surgery, with median recurrence times of 7 to 18 months reported in large series.

Improved and more frequent postoperative imaging has demonstrated more substantial rates of isolated or co-synchronous pelvic failure than historically appreciated. The most important risk factors for pelvic failure are the presence of pT3–4 disease, positive soft-tissue margins, and whether greater than 10 benign or malignant lymph nodes were identified in the lymphadenectomy specimen. These factors have been combined to define three risk groups for pelvic failure: low risk, less than pT3 disease; intermediate risk, pT3–4, negative margins, and greater than 10 lymph nodes identified; high risk, pT3–4 with positive margins or less than 10 lymph nodes identified. This model consistently stratifies pelvic failure risk in geographically and temporally diverse radical cystectomy cohorts, with 5-year pelvic failure rates of approximately 8% for low-risk groups, 19% to 21% for intermediate-risk groups, and 41% to 46% for high-risk groups (Christodouleas et al., 2014; Ku et al., 2014; Novotny et al., 2015).

Neoadjuvant Therapy for Muscle-Invasive Bladder Cancer

Nearly 50% of patients with muscle-invasive bladder cancer treated with cystectomy alone will progress to metastatic disease (Ghoneim et al., 2008; Stein et al., 2001). Clearly, surgery alone is not sufficient therapy in a large number of patients with invasive bladder cancer. Systemic therapy with cisplatin-based chemotherapy has been shown to provide response rates in multiple bladder cancer studies since the mid-1980s (Stenzl et al., 2009; Sternberg et al., 1985). Since the initial reports of its usefulness in muscle-invasive bladder cancer, there have been multiple randomized controlled studies undertaken to define further the effectiveness of neoadjuvant cisplatin-based chemotherapy in advance of cystectomy. Unfortunately, many of these studies have been hampered by inadequate power and a lack of standardization of surgical approaches to demonstrate clearly a survival advantage with neoadjuvant chemotherapy in most of these studies when they are evaluated individually.

There are several arguments for cisplatin-based chemotherapy in the neoadjuvant setting for patients with muscle-invasive bladder cancer. First, systemic chemotherapy is often better tolerated before surgery, rather than after surgery when patients may experience a delay in chemotherapy administration because of complications or debilitation. Second, patients who present with micrometastatic disease will receive therapy in a timelier fashion when their burden of disease is potentially low. Third, neoadjuvant chemotherapy has the potential to downstage bulky and locally advanced tumors, allowing for a higher likelihood for negative surgical margins that are a known predictor of local recurrence following cystectomy. Finally, neoadjuvant chemotherapy allows the clinician to assess each individual's response to therapy. A disadvantage of neoadjuvant chemotherapy is a delay in definitive local therapy for patients who do not respond to chemotherapy and thus experience disease progression.

The European Organization for Research and Treatment of Cancer (EORTC) and the Medical Research Council (MRC) performed the largest neoadjuvant chemotherapy trial in bladder cancer. This study evaluated the benefit of three cycles of neoadjuvant cisplatin, methotrexate, and vinblastine in 976 patients before radiation or cystectomy (International Collaboration of Trialists, 1999). The study was designed to detect an absolute improvement in survival of 10%

with a power of 90% and a type 1 error of 5%. Eighty percent of the 491 patients who were assigned to the chemotherapy arm completed three cycles. The study was performed at 106 centers, and the decision as to whether patients received radiation or cystectomy was at the discretion of the investigators. Chemotherapy-related mortality was reported to be 1%. At the time of the initial analysis, there was a trend noted toward improved survival in the neoadjuvant chemotherapy arm (HR 0.85, 95% CI 0.71 to 1.02; $P = .075$) with a median follow-up of 4 years. This translated into a nonsignificant absolute difference in survival of 5.5% at 3 years with survival rates of 50% for those who did not receive chemotherapy compared with 55.5% for those who did. The results of this trial were updated in 2011, with a median patient follow-up of 8 years (Hall, 2002). The updated survival results were notable for a statistically significant 16% reduction in the risk of death for patients in the chemotherapy arm (HR 0.84, 95% CI 0.72 to 0.99; $P = .37$). The estimated 10-year survival in the chemotherapy arm was 36% compared with 30% in the control arm, translating to a 6% absolute survival benefit (Griffiths et al., 2011). Limitations of the EORTC/MRC trial when compared with current clinical practice include the fact that cisplatin, methotrexate, and vinblastine is not considered a standard of care for muscle-invasive bladder cancer and has not been compared directly to methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin (MVAC). Additionally, approximately 40% of patients in both the chemotherapy arm and local therapy arm received radiation and not radical cystectomy.

The intergroup trial (Southwest Oncology Group [SWOG] 8710) randomized 317 patients to three cycles of neoadjuvant MVAC versus cystectomy alone for CT2-T4aN0M0 bladder cancer (Grossman et al., 2003a). Eighty-two percent of patients randomized to chemotherapy ultimately underwent a cystectomy with a mean time to surgery of 115 days. Thirty-eight percent of the chemotherapy patients achieved pT0 status at the time of cystectomy compared with 15% of the controls ($P < .001$). The median OS time in the chemotherapy group was 77 months compared with 46 months in the cystectomy-only group. The 5-year OS rates were 57% and 43% in the chemotherapy and cystectomy-only arms, respectively. However, the survival results failed to reach statistical significance ($P = .06$). Notably, patients who were downstaged to pT0 achieved excellent outcomes, with 80% alive at 5 years compared with 40% of patients with residual disease. A secondary analysis of the SWOG 8710 data compared subgroup outcomes for patients with pure urothelial carcinoma versus mixed histologic subtypes (Scosyrev et al., 2011). The authors reported a survival advantage in the mixed histology subgroup that received neoadjuvant chemotherapy. Given the fact that this was a secondary subgroup analysis, it is difficult to draw definitive conclusions; however, this analysis does suggest that patients with mixed histology should be considered for neoadjuvant chemotherapy. Other randomized trials of neoadjuvant chemotherapy for bladder cancer are summarized in Table 137.4.

TABLE 137.4

Randomized Trials of Neoadjuvant Chemotherapy

STUDY	NO. OF PATIENTS	NEOADJUVANT ARM	CONTROL ARM	STAGE	SURVIVA RATE
EORTC/MRC (International Collaboration of Trialists, 1999)	976	CMV + RC/RT	RC/RT	T2-4aNxM0	10-year OS 36% vs. 30% (*P* = .037)
Nordic I (Malmström et al., 1996)	325	CA + RT + RC	RT + RC	T1-4aNxM0	5-yearr OS 59% vs. 51% (*P* = .1)
Nordic II (Sherif et al., 2002)	317	CM + RC	RC	T2-4aNxM0	5-year OS: 53% vs. 46% (*P* = .24)
SWOG (Grossman et al., 2003a, 2003b)	317	MVAC + RC	RC	T2-4aN0M0	5-year OS: 57% vs. 43% (*P* = .06)

Coppin et al., 1996	99	Cis + RT/RC	RT + RC	T2-4bN0-3M0	3-year OS: 47% vs. 33% (*P* = .34)

CA, Cisplatin and doxorubicin; *CarboMV,* carboplatin, methotrexate, and vinblastine; *Cis,* cisplatin; *CM,* cisplatin and methotrexate; *CMV,* cisplatin, methotrexate, and vinblastine; *CUETO,* Spanish Oncology Group; *EORTC/MRC,* European Organization for Research and Treatment of Cancer/Medical Research Council; *GISTV,* Gruppo Italiano per lo Studio dei Tumori della Viscica (Italian Bladder Cancer Study Group); *GUONE,* Gruppo Uro-Oncologico del Nord-Est (North-Eastern Uro-Oncological Group, Italy); *MVAC,* methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin; *MVEC,* methotrexate, vinblastine, epirubicin, and cisplatin; *OS,* overall survival; *RC,* radical cystectomy; *RT,* radiation therapy; *SWOG,* Southwest Oncology Group; *WMURG/ABCSG,* West Midlands Urological Research Group/Australian Bladder Cancer Study Group.

Most of the trials reported in the literature have failed to demonstrate a statistically significant survival advantage for those patients who received neoadjuvant chemotherapy. Contributing to these findings are inherent limitations to the trial designs including small sample sizes, varying and sometimes suboptimal chemotherapy protocols, premature closure, and inadequate follow-up (Sylvester and Sternberg, 2000). In an attempt to clarify further the precise benefit of neoadjuvant chemotherapy, several investigators have performed meta-analyses of the current chemotherapy trials. The Advanced Bladder Cancer (ABC) Meta-analysis Collaboration (2005a, b) undertook the largest meta-analysis. This report was an update to the group's previous meta-analysis in 2003, now including the SWOG 8710 trial data for a total of 11 randomized neoadjuvant chemotherapy trials. Individual patient data were analyzed from 3005 patients making up 98% of patients from all known eligible trials. The trials were grouped based on the use of single-agent platinum or platinum-based combination chemotherapy. There was a significant benefit in favor of platinum-based combination chemotherapy with regard to OS (HR 0.86, 95% CI 0.77 to 0.95, $P = .003$). This resulted in an absolute survival benefit of 5%, improving OS from 45% to 50% at 5 years. Disease-free survival data were available on 2846 patients from 10 trials. There was a significant benefit in the platinum-based combination chemotherapy group (HR 0.78, 95% CI 0.71 to 0.86, $P <. 0001$). The 5% survival benefit was consistent across patient subgroups including age, sex, clinical stage, and performance status.

The Cancer Care Ontario Program in Evidence-based Care Practice Guidelines Initiative also reported a neoadjuvant chemotherapy meta-analysis (Winquist et al., 2004). The authors reviewed 16 randomized-controlled trials (3315 patients) and identified 11 (2605 patients) with suitable data. The pooled HR was 0.90 (95% CI 0.78 to 0.96, $P = .02$) in favor of neoadjuvant chemotherapy. When the eight trials using cisplatin-based combination chemotherapy were analyzed, the pooled HR was 0.87 (95% CI 0.78 to 0.96, $P = .006$), consistent with an OS benefit of 6.5% (95% CI 2 to 11).

Based on the randomized trial results and subsequent meta-analyses, cisplatin-based neoadjuvant chemotherapy is associated with an OS advantage of 5% to 6% and a pathologic complete response rate of 30% to 40%. Currently the NCCN guidelines recommend that clinicians strongly consider neoadjuvant cisplatin-based chemotherapy for cT2N0M0 patients and recommend neoadjuvant cisplatin-based chemotherapy for cT3–T4aN0M0 patients. The European Association of Urology guidelines currently recommend neoadjuvant chemotherapy for T2–T4aN0M0 patients and also note that it should always be a cisplatinum-based combination regimen. Despite the evidence supporting neoadjuvant chemotherapy, it continues to be underused. An analysis of 7161 patients with stage III bladder cancer within the National Bladder Cancer Database noted that only 11.6% of patients received perioperative chemotherapy, of which 1.2% were in the neoadjuvant setting (David et al., 2007). SEER-Medicare data have also demonstrated a lack of penetrance of neoadjuvant chemotherapy in the setting of muscle-invasive disease (Porter et al., 2011).

Neoadjuvant radiation was commonly performed in the 1970s and 1980s but fell out of favor after the introduction of cisplatin-based neoadjuvant therapy, which does not complicate surgery or limit surgical options as much as radiation. There have been multiple attempts to study the role of neoadjuvant radiation including at least five small prospective randomized trials (Anderstrom et al., 1983; Blackard and Byar, 1972; Ghoneim et al., 1985; Slack et al., 1977; Smith et al., 1997) but none were able to convincingly demonstrate a benefit.

Adjuvant Therapy for Muscle-Invasive Bladder Cancer

Patients with pT3–T4 or node-positive disease are known to be at high risk for recurrence following cystectomy. Adjuvant chemotherapy has been used in this population in an attempt to treat micrometastatic disease and to improve survival. The rationale for systemic chemotherapy following cystectomy includes the fact that it allows for immediate local treatment with cystectomy and avoids any delay in treatment in patients with chemotherapy-resistant tumors (Sternberg and Sylvester, 2014). The availability of final pathology also allows clinicians to select patients at the highest risk for failure who are most likely to benefit while sparing those who are less likely to progress from the side effects of systemic chemotherapy. Additionally, the role of molecular markers to predict disease aggressiveness and therapeutic response is likely to expand in the future. Cystectomy in this case would provide adequate tissue to direct individualized therapy based on molecular and genomic analysis.

A major limitation of adjuvant chemotherapy is that it is often difficult or impossible for patients to undergo systemic therapy following cystectomy secondary to surgical deconditioning, deteriorating renal function, or perioperative complications (Donat et al., 2009; Hall et al., 1996). For example, in a randomized trial evaluating adjuvant chemotherapy for pT3–4/N+ disease, 25% of patients randomized to the chemotherapy arm did not receive such therapy (Skinner et al., 1991). Adjuvant chemotherapy trials have been hampered by small overall numbers and difficult patient accrual, which has limited the ability to draw definitive conclusions regarding the overall effectiveness of this approach.

Randomized Trials of Adjuvant Chemotherapy

There have been multiple randomized trials set forth to define the role of adjuvant chemotherapy (Table 137.5). Unfortunately, these trials have not provided sufficient evidence to support adjuvant chemotherapy, and this is because of low numbers, difficulty with patient accrual, early termination of the trials, and flawed statistical design. The University of Southern California (USC) group reported the first prospective, randomized trial to demonstrate a survival benefit with adjuvant chemotherapy (Skinner et al., 1991). A total of 91 patients with pT3–4 or N+ disease following cystectomy were randomized to cisplatin-based chemotherapy versus observation. Three-year time to progression was significantly better in the chemotherapy group, with 70% of patients free from disease compared with 46% assigned to observation. Median survival was also significantly improved in the chemotherapy arm (4.3 years vs. 2.4 years; P = .0062). Although this trial did demonstrate an advantage in favor of adjuvant chemotherapy, it has been criticized for several reasons. First, the overall number of patients is small, which limits statistical power. Additionally, chemotherapy regimens were not standardized and included a cisplatin, cyclophosphamide, and doxorubicin (Adriamycin) (CISCA)-like regimen, single-agent cisplatin, and chemotherapy regimens selected by clonal assays. This trial also highlighted the difficulty of administering chemotherapy after cystectomy with 25% of patients who were assigned to receive chemotherapy and who were not receiving therapy.

TABLE 137.5

Adjuvant Chemotherapy Trials Following Cystectomy

INVESTIGATOR	NO. OF PATIENTS	REGIMEN	CHEMO	NO CHEMO	RESULTS/SHO

CAP, Cisplatin, cyclophosphamide, and doxorubicin; *CISCA,* cisplatin, cyclophosphamide, and doxorubicin (Adriamycin); *CM,* cisplatin and methotrexate; *CMV,* cisplatin, methotrexate, and vinblastine; *DDP,* diamminedichloroplatinum (cisplatin); *GC,* gemcitabine and cisplatin; *MVAC,* methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin; *MVEC,* methotrexate, vinblastine, epirubicin, and cisplatin; *TTP,* time to progression.

A German trial randomized 49 patients with pT3b–4a and/or N+ disease to receive three cycles of MVAC or MVEC (methotrexate, vinblastine, epirubicin, and cisplatin) (Stockle et al., 1992, 1995). A total of 26 patients were randomized to chemotherapy, and 69% received it. Three-year disease-free survival was significantly improved in the chemotherapy arm (63% vs. 13%, $P = .002$), and based on these results the study stopped early. This study was updated with a total of 83 patients (38 received chemotherapy after the close of the trial based on the interim analysis). Ten-year follow-up data maintained an advantage in the chemotherapy group with regard to progression-free survival (44% vs. 13%, $P = .02$) and DSS (42% vs. 17%, $P = .007$). Although there was a trend toward an OS benefit in the adjuvant chemotherapy arm, this was not statistically significant (27% vs. 17%, $P = .07$). Ultimately, 92% of patients in the observation arm showed evidence of tumor progression compared with 27% who received chemotherapy. Much like the USC trial, this trial has also been widely criticized. Overall, the number of patients is small because of early closure of the trial after interim analysis. Many patients in the observation group were not offered chemotherapy at the time of disease progression and, as one would expect, not all patients randomized to chemotherapy ultimately received such therapy.

Since the mid-2000s, there have been several attempts at large-scale adjuvant chemotherapy trials, most of which have been presented in abstract form. Unfortunately, the majority of these studies have been hampered by poor accrual. The results of an Italian adjuvant chemotherapy, multicenter, randomized phase III trial have been published (Cognetti et al., 2012). This study randomized 194 patients with pT2G3, pT3–4, N0–2 urothelial carcinoma to observation ($N = 92$) versus four cycles of chemotherapy ($N = 102$). The chemotherapy cohort was randomly assigned to one of two regimens; either gemcitabine 1000 mg/m^2 days 1, 8, and 15 and cisplatin 70 mg/m^2 day 2 or the same gemcitabine schedule plus cisplatin 70 mg/m^2 day 15, every 28 days. With a median follow-up of 35 months, the 5-year OS was 48.5% with no difference between the chemotherapy and observation arms ($P = .24$). There was also no statistical difference in disease-free survival in the observation (42.3%) and chemotherapy arms (37.2%). Only 62% of patients received the planned course of chemotherapy, however. The initial study was designed to randomize 610 patients in a 1 : 1 fashion but was closed early because of poor accrual. The smaller sample size resulted in significant underpowering of the study in detecting a significant difference between adjuvant chemotherapy and observation.

The Cancer and Leukemia Group B (CALGB) trial randomized patients following cystectomy with acceptable renal function to either a rapid-cycling regimen of chemotherapy with four cycles of doxorubicin-gemcitabine administered at 14-day intervals with granulocyte colony-stimulating factor (G-CSF) support followed by four cycles of paclitaxel-cisplatin provided at 21-day intervals compared with adjuvant gemcitabine with cisplatin in a 4-week cycle (Bajorin, 2001). The accrual goal in this trial was 800 patients; however, the study was terminated for poor accrual, and ultimately fewer than 100 patients enrolled. Similarly, the EORTC-30994 trial randomized patients with pT3–4 and/or N+ disease with acceptable renal function to either four cycles of either gemcitabine/cisplatin, MVAC, or high-dose intensity (HD) MVAC versus observation. The accrual goal for this trial was 660 patients, but it closed as a result of poor accrual enrolling a total of 278 patients (Sternberg et al., 2001c). The USC/SWOG International trial randomized 114 patients with pT1–2, N0, p53-positive tumors to three cycles of adjuvant MVAC or observation (Stadler et al., 2009). A total of 114 patients were randomized, but further accrual was halted after interim analysis showed no difference in recurrence-free survival. Additionally, 67% of those randomized to MVAC received all three cycles, and 12% received none. The Spanish Oncology Genitourinary Group (SOGUG) 99/01 trial randomized patients with pT3–4 or node-positive disease to four cycles of paclitaxel, gemcitabine, and cisplatin versus observation. At a median follow-up of 51 months, a 5-year OS advantage was noted with chemotherapy (60% vs. 31%, $P < .0009$); however, the trial was stopped prematurely because of poor accrual after 7 years after randomizing 142 patients, which was well below the target of 340.

Similar to the neoadjuvant chemotherapy, the Advanced Bladder Cancer (ABC) Meta-analysis Collaboration evaluated the effect of adjuvant chemotherapy reviewing 11 randomized trials and ultimately including 6 trials with a total of 491 patients (ABC Meta-analysis Collaboration, 2005a, 2005b). The overall HR for survival from this meta-analysis was 0.75 (95% CI 0.60 to 0.96, $P = .019$), suggesting a 25% relative reduction in the risk for death in favor of adjuvant chemotherapy compared with controls. This translated to a 9% absolute survival benefit at 3 years. Despite the positive findings, the authors of the meta-analysis point out that insufficient evidence remains to base treatment decisions reliably. Notably, there were major deficiencies in the trials included in the meta-analysis such as small sample sizes, early closure of trials, limitations in statistical analysis, and differences in the way disease-free survival was defined (Sternberg and Collette, 2006).

Despite the efforts of the trials outlined earlier, the evidence for adjuvant chemotherapy is lacking. An updated meta-analysis including 945 patients noted that adjuvant chemotherapy seems to be most beneficial to patients with node-positive disease; however, this meta-analysis was limited by many of the same issues outlined earlier (Leow et al., 2014). The available evidence suggests that perioperative chemotherapy does confer a survival benefit for bladder cancer patients with stronger evidence available in the neoadjuvant approach. The optimal approach and benefit to systemic chemotherapy in the adjuvant setting remains incompletely defined, and based on the difficulty with patient accrual in past trials it may remain unanswered. Currently the NCCN guidelines favor neoadjuvant chemotherapy instead of adjuvant chemotherapy based on higher-level evidence data; however, the guidelines do suggest considering adjuvant chemotherapy in the setting of pT3–4 or node-positive disease based on the available data. The EAU guidelines currently recommend adjuvant chemotherapy within clinical trials but not as a routine therapeutic option, as randomized trials and meta-analyses have not provided sufficient evidence to support routine use.

Adjuvant Chemoradiation

Multiple studies have demonstrated that patients with locally advanced disease (pT3–4) have high pelvic failure rates (20% to 40% at 5 years) and that perioperative chemotherapy does not significantly improve that risk (Baumann et al., 2013a; Christodouleas et al., 2014). Moreover, after pelvic failure is identified, outcomes are quickly catastrophic with a median survival of approximately 9 months (Baumann et al., 2013a,b). There have been several clinical trials that evaluated the potential benefits of adjuvant radiation. A three-arm randomized trial performed at the National Cancer Institute in Cairo in the 1980s compared adjuvant radiation therapy alone (using two different radiation techniques) versus observation for patients with negative soft-tissue surgical margins but high risk for local failure following radical cystectomy alone (Zaghloul et al., 1992). This study demonstrated a significant improvement in pelvic control and 5-year OS for the two radiation therapy arms. The generalizability of that trial for populations outside Egypt has been questioned because 80% of the patients had squamous cell carcinoma and only 20% urothelial carcinoma, although the outcomes appeared similar regardless of histology. Because of this study, adjuvant radiation was commonly employed in Egypt and other countries where squamous cell carcinoma of the bladder is prevalent. A follow-up randomized phase II study, also performed by the National Cancer Institute in Cairo, compared adjuvant chemotherapy alone (four cycles of gemcitabine and cisplatin [gem/cis]) versus adjuvant sandwich chemoradiation (sequential therapy with two cycles of gem/cis, radiation, and then two additional cycles of gem/cis) (Zaghloul et al., 2018). This small study ($N = 120$) included a majority of urothelial carcinoma patients and demonstrated a significant improvement in 2-year pelvic-failure–free survival favoring the chemoradiation arm (96% vs. 69%, $P < 0.1$) and non–statistically significant higher rates of disease-free (68% vs. 56%, $P = 0.07$) and OS (71% vs. 60%, $P = 0.11$).

Because adjunctive radiation could substantially increase the risk for postoperative small bowel obstruction (Baumann et al., 2015), adoption of adjuvant radiation therapy should proceed cautiously for patients for locally advanced disease. The strongest case for its use can be made for patients with positive soft-tissue surgical margins, but there are several ongoing prospective studies specifically studying its role for patients with pT3–4 primary tumors, less than 10 nodes identified, and N+ disease.

Bladder Preservation

Although radical cystectomy remains the standard of care for patients with muscle-invasive bladder cancer, it is a major operative procedure with significant risk for perioperative morbidity and mortality (Shabsigh et al., 2009). Data from Medicare claims have shown radical cystectomy to have the second highest 30-day readmission rate compared with other urologic and nonurologic procedures (Goodney et al., 2003). The high incidence of perioperative complications, coupled with a classically older patient population with multiple medical comorbidities, has led patients and clinicians to seek alternatives to cystectomy. Bladder preservation is a curative intent paradigm that should be considered in two distinct populations: (1) patients who have high operative risks as a result of comorbidities and frailty and (2) patients who are fit for radical cystectomy but have limited burden of disease, adequate normal bladder urothelial and function, and are motivated to retain their bladder.

The most rigorously studied approach to bladder preservation is trimodality therapy: a maximal safe and ideally visibly complete TUR, chemotherapy, and radiation, but there are other nonradical approaches that a clinician should consider, especially in older, frail patients.

Two basic strategies for trimodal bladder preservation exist: split-course and continuous-course therapy. Split-course therapy is based on the premise of mid-treatment restaging and is only appropriate for patients who are surgically fit and thus eligible for an immediate salvage cystectomy. In a split-course approach, patients are administered induction chemoradiation therapy to approximately 40 Gy, which is followed by restaging with cross-sectional imaging and endoscopic evaluation. If persistent *invasive* disease is noted, radical cystectomy is recommended. Those without persistent invasive disease undergo consolidative chemoradiotherapy to approximately 60 to 64 Gy. As the name implies, continuous-course treatment involves a full course of chemoradiation therapy followed by an endoscopic restaging examination 3 to 4 months after therapy to allow time for an adequate response to therapy. Continuous-course treatment is an appropriate option for both surgically fit and unfit patients. Given the same total dose, continuous-course treatment is more intensive than split-course treatment because continuous-course therapy is completed over a shorter period, which limits the opportunity for both tumor and normal tissue cell repopulation. Regardless of approach, the benefits of concurrent sensitizing chemotherapy during the course of radiation is now well-established. In the largest randomized study of its kind, James et al. demonstrated that mitomycin and 5-fluorouracil (5-FU) given concurrently with radiation was superior to radiation alone with respect to 2-year locoregional disease-free survival (67% vs 48%) without significantly worse late toxicity (James et al., 2012).

Another factor that likely affects the efficacy of trimodality therapy is the quality of the TUR. Studies suggest superior 5- and 10-year OS rates for patients with visibly complete TURs (57% and 39%) compared with those without complete resection (43% and 29%) before trimodal therapy, though these differences are confounded by selection bias. The rates of radical cystectomy for visibly complete resections are lower (11%) compared with incomplete resections (42%) (Efstathiou et al., 2012).

In some patients with severe comorbidities and short life-expectancies, even trimodality bladder preservation may be inappropriately aggressive. In such cases, single-modality therapy can be considered. The outcomes of trimodality and single-modality therapies are described in detail in the following sections.

Trimodal Therapy for Surgically Fit Patients

Trimodality bladder preservation and radical cystectomy with or without perioperative chemotherapy for surgically fit patients have not been compared in randomized trails, so we cannot draw strong conclusions about the relative merits of these very different treatment approaches. Prospective studies suggest that well-selected fit patients have similar long-term cancer control outcomes with trimodality approaches. Appropriate candidates are those with a limited burden of disease and adequate normal bladder urothelial and function and who are motivated to retain their bladder. In general, a patient is considered to have a limited burden of disease if the bladder tumor is unifocal and small (<4 cm in maximal dimension) without frank extravesicular extension on imaging (i.e., not cT3b), does not cause hydronephrosis, and can be gross totally resected by TUR. It has been estimated that 6% to 19% of patients presenting with muscle-invasive bladder cancer meet strict criteria for “limited burden of disease” (Smith et al., 2013). It is also important to consider whether a patient's bladder is worth preserving. If a fit patient has poor baseline bladder function or diffuse CIS that is at risk for generating additional invasive tumors, then the patient's quality of life may be improved by a radical resection. The patient must be motivated to retain his or her bladder because 25% to 30% of patients will ultimately have salvage cystectomy in the long-term as a result of muscle-invasive recurrences (Efstathiou et al., 2012; Sell et al., 1991). It should be noted that there is limited very long-term data (>15 years) on outcomes after trimodality therapy. Given the known very late sequelae of radiation (secondary malignancies in particular), fit patients with long life-expectancies are not ideal candidates for radiation. The major chemoradiation bladder preservation trials for surgically fit patients are summarized in Table 137.6.

TABLE 137.6

Major Prospective Trimodal Bladder Preservation Studies

STUDY	NO. OF PATIENTS	STAGE	CHEMOTHERAPY	RT	CR RATE	SALVAGE CYSTECTOMY RATE
Housset et al., 1993	54	T2–4N0–1Mx	Cisplatin + 5-FU + 4	44 Gy	74%	NA
Shipley et al., 1998	62	T2–4aN0Mx	Cisplatin + 3	64.8 Gy	60%	25.8%

Tunio et al., 2012	200	T2–4N0Mx	Weekly cisplatin	65 Gy	93%	
James et al., 2012	182	T2–4aN0Mx	5-FU, MMC + 2	55 or 64 Gy		11.4%

The Massachusetts General Hospital (MGH) and the Radiation Therapy Oncology Group (RTOG) have developed a split-course approach for surgically fit patients. The RTOG has completed six prospective protocols using the split-course paradigm (total of 468 patients in one phase III and five phase II trials) using slightly different techniques and chemotherapy regimens to evaluate the efficacy of trimodal therapy for muscle-invasive disease. Across these studies, the complete response rate observed at the treatment break was 69%. The 5-year OS and DSS rates were 57% and 71%, respectively. The 10-year OS and DSS rates were 36% and 65%, respectively. Of patients alive at 5 years, 80% had an intact bladder. Overall, 21% of fit patients started on split-course therapy had a salvage cystectomy, 62% of whom had it after the induction phase only because of incomplete response assessment. Two percent had salvage cystectomy resulting from causes other than recurrent tumor, presumably caused by treatment-related complications. Among patients who had a salvage cystectomy, the 5-year OS and DSS were 45% and 60%, respectively, and the 10-year OS and DSS were 18% and 47%, respectively. It is worth noting that more recent North American trimodality trial proposals for surgically fit patients are transitioning away from split-course therapy in favor of continuous-course therapy, likely because of favorable reports from European continuous-course studies, especially BC 2001. In BC 2001, 360 patients (both fit and unfit for surgery) were randomized to continuous-course chemoradiation therapy compared with continuous-course radiation therapy alone. Patients in the chemoradiation cohort received mitomycin followed by 5-FU in conjunction with radiation. At 2 years, the locoregional disease-free survival in the chemoradiation therapy group was 67%. The 5-year OS rate was 48%, and there was no significant increase in toxicity compared with the radiation-only group (James et al., 2012).

Trimodality Therapy for Surgically Unfit Patients

There are no uniformly accepted criteria defining patients who are unfit for radical cystectomy. When considering which patients may not be suitable for radical cystectomy, an important concept to bear in mind is the *therapeutic break-even point.* The therapeutic break-even point reflects the time it would take for a patient to realize the benefits of improved locoregional control (conferred by radical cystectomy) given a short-term increase in treatment-related mortality. If the estimated break-even point for radical cystectomy is longer than the patient's life expectancy, then the short-term risks associated with surgery likely outweigh the potential long-term benefits. Of course, estimating the therapeutic break-even point is a challenge because it requires estimating the marginal short-term mortality costs and long-term mortality benefits of radical cystectomy compared with trimodality therapy, both estimates of which are sensitive to patient factors such as patient frailty (Chappidi et al., 2016) and tumor burden. Tools that provide useful benchmarks for estimating the therapeutic break-even point are under development (Baumann et al., 2018). However, because there is no perfect way to estimate the components of the break-even point algorithm, the best strategy for determining whether a patient is fit for radical cystectomy involves a multidisciplinary evaluation with an emphasis on patient preferences and shared decision making.

The outcomes of surgically unfit patients treated with definitive chemoradiation are surely poorer than those of surgically fit patients. However, estimating outcomes for surgically unfit patients is challenging because very few studies exclusively enroll unfit patients or identify them up front. Because trimodality bladder preservation is rarely employed in the United States, unadjusted results of trimodality therapy from observational national registries likely primarily reflect outcomes of surgically unfit patients. In a study of unadjusted trimodality outcomes of patients with the SEER registry (from 1995 to 2005), 5-year OS and DSS for patients receiving trimodality therapy was approximately 30% and 55%, respectively (Bekelman et al., 2013).

Single-Modality Treatment

Radiation Monotherapy

For clarity of presentation in this section, the term *radiation monotherapy* will also be used to describe studies in which debulking TUR was performed before radiation. The rationale for this terminology is that it is often difficult to ascertain exactly how complete the debulking TUR was that was performed across various series, which likely varies from institution to institution. It should be noted at the outset that two prospective randomized trials and many retrospective studies have firmly established the superiority of radiation when given concurrently with sensitizing systemic therapy. Several sensitizing regimens have been validated, including mitomycin/5-FU, nicotinimide/carbogen, cisplatin/5-FU, and gemcitabine alone, so radiation monotherapy should be reserved only for patients with very poor performance status or severe comorbidities. Indeed, radiation monotherapy should reserve for situations that are quasi-palliative. That said, there is extensive literature establishing the efficacy of radiation monotherapy. Rödel et al. (2002) reported on 126 patients treated with radiation monotherapy. The authors reported 5- and 10-year OS rates of 40% and 19%, respectively, which were inferior to results obtained with a chemoradiation regimen. As with cystectomy series, response to radiation monotherapy is largely dependent on the stage of disease. Local control rates have been reported to be as low as 27% for patients with T3 disease (Pollack and Zagars, 1996). BC 2001 demonstrated more favorable results for radiation monotherapy (2-year disease-free survival of 54% and 5-year OS of 35%); however, improved survival was noted in patients randomized to combined chemoradiation therapy (James et al., 2012). Prognostic factors for local failure after radiation monotherapy are similar to those of radical TUR, including tumor multifocality, presence of hydronephrosis, and higher clinical T stage.

Combined external beam radiation and brachytherapy have also been explored as possible bladder preservation techniques. Using a technique of 30 Gy of external beam radiation followed by 40 Gy of brachytherapy, Nieuwenhuijzen et al. (2005) reported 5- and 10-year OS rates of 62% and 50%, respectively, with 5- and 10-year DSS rates of 73% and 67%, respectively. The local control rate at 5 years was 73%. Survival results were similar to radical cystectomy patients at the same institution during that period; however, this was not a prospective, randomized trial, and therefore definitive conclusions compared with radical cystectomy outcomes are not valid. Additionally, patients with high-grade T1 bladder cancer were also included in this analysis, limiting its generalizability to a population of strictly muscle-invasive patients.

Radical Transurethral Resection

Primary support for radical TUR as a single-modality therapy for patients with T2 disease is largely based on the finding of p0 disease in approximately 10% of patients treated with radical cystectomy alone. A major limitation of radical TUR monotherapy is the significant risk for occult extravesical disease noted in patients with clinical T2 disease. Pathologic T3 and pT4 disease has been noted in cT2 cystectomy specimens in up to 40% and 9% of patients, respectively (Karakiewicz et al., 2006b). Additionally, multiple radical cystectomy series have consistently shown an approximately 25% risk for occult nodal metastasis at the time of surgery (Stein et al., 2001). Therefore, TUR monotherapy in upward of 50% of patients presenting with muscle-invasive bladder cancer would be undertreatment. In highly selected patients, however, several authors have reported reasonable long-term results with this approach.

In a series of 133 patients and a minimum of 15-year follow-up, radical TUR was reported to have a DSS of 82%, 80%, and 77% and progression-free survival of 76%, 65%, and 58% at 5, 10, and 15 years, respectively (Solsona et al., 2010). Patients were excluded from this approach if they presented with tumors greater than 3 cm or hydronephrosis. Patients with CIS at the time of TUR were treated with intravesical therapy. Wide resection of the TUR site was also performed at 3 and 6 months, and the patients underwent intensive endoscopic surveillance every 3 months for 2 years, every 6 months for 3 years, and annually thereafter. Long-term results with TUR monotherapy (≥10 years) have also been reported by the MSKCC group (Herr, 2001). This cohort of 99 patients with muscle-invasive disease all underwent a restaging TUR that demonstrated either no tumor (74%) or residual non–muscle-invasive disease (26%) before enrolling in a bladder-preservation protocol. The 5- and 10-year DSS rates were 82% and 76%, respectively, with actual bladder preservation rates of 67% and 57%, respectively. Patients with cT0 disease at the time of restaging TUR achieved the best long-term responses with a 10-year DSS of 82% compared with 57% for those with residual non–muscle-invasive disease. One-third of the patients ultimately developed muscle-invasive bladder cancer, of which nearly one-half (47%) died of disease. The MD Anderson group has also reported on a smaller cohort of patients treated with TUR monotherapy and a median follow-up of 2.5 years (Leibovici et al., 2007). Criteria for TUR monotherapy in this cohort included no residual tumor at the resection site on repeat TUR, normal examination under anesthesia, normal upper urinary tract evaluation, and no urethral involvement. Of the 327 patients who presented with muscle-invasive bladder cancer during a 6-year period, 35 (11%) met entry criteria and 27 elected for bladder preservation. With a median follow-up of 2.5 years, 44% remained free from disease, whereas 56% experienced a recurrence. Of the 15 patients who had a subsequent recurrence, one presented with node-positive disease. Eight patients ultimately underwent cystectomy, of which five showed extravesical disease on final pathology.

Although specifically selected individuals can achieve a durable response with radical TUR, most patients presenting with muscle-invasive bladder cancer are not appropriate candidates and will not be cured with TUR monotherapy. If a patient is going to elect TUR monotherapy, that patient should be properly informed regarding the risk for recurrent disease and should be appropriately selected based on clinical criteria including a negative restaging TUR, no hydronephrosis, no evidence of adenopathy, tumor size less than 3 cm, and lack of multifocal disease.

Partial Cystectomy

Compared with radical TUR, partial cystectomy offers two distinct advantages. First, a full pelvic lymphadenectomy can be performed that allows for complete staging. Second, the full thickness of bladder wall and associated perivesical fat can be removed. Historically, partial cystectomy was associated with poor outcomes including 5-year OS rates as low as 24% (Kassouf et al., 2006) and high rates of local recurrence and wound recurrences. However, with more stringent selection criteria, partial cystectomy can be associated with acceptable oncologic outcomes.

Ideal candidates for partial cystectomy include those with small, solitary tumors amenable to wide resection with 2-cm margins. Ideally the tumor should be away from the ureteral orifices to avoid reimplantation. It is imperative that the tumor is in a location that allows for complete resection while maintaining adequate functional bladder capacity. Partial cystectomy is also the treatment of choice for urachal adenocarcinoma; however, these lesions are distinct pathologic entities from urothelial carcinoma, and the studies that follow are specific to urothelial carcinoma. The presence of CIS is considered by most to be a contraindication to partial cystectomy, and random bladder biopsies can be performed preoperatively. The MSKCC group has also recommended the routine use of intraoperative frozen sections and proceeding with radical cystectomy if a negative margin cannot be achieved (Holzbeierlein et al., 2004). Using strict selection criteria, long-term oncologic results can approach that of radical cystectomy (Holzbeierlein et al., 2004; Kassouf et al., 2006).

Contemporary series demonstrate non–muscle-invasive recurrences in 12% to 50% of cases, muscle-invasive recurrences in 17% to 57%, and metastatic recurrence in 14% to 52%, respectively (Holzbeierlein et al., 2004; Kassouf et al., 2006; Smaldone et al., 2008). The 5-year OS, recurrence-free survival, and DSS in the same series were 67% to 70%, 39% to 62%, and 84% to 87%, respectively. Bladder intact rates and bladder intact without evidence of disease rates were reported by the MSKCC and the MD Anderson groups as 65% to 74% and 49% to 67%, respectively. Salvage cystectomy may be necessary in up to one-fourth of patients and can be associated with a cure in 75% of cases. It is important to note the presence of late recurrence of muscle-invasive disease in three patients (41, 44, and 138 months) in the MD Anderson experience, highlighting the need for long-term follow-up in such patients. There are risk factors for recurrence after partial cystectomy.

Partial cystectomy has also been reported in combination with neoadjuvant chemoradiation therapy. Koga et al. (2012) reported on 46 patients with muscle-invasive bladder cancer who were treated with this approach. Selection criteria included a solitary tumor composing less than 25% of the total bladder area, no involvement of the bladder neck or trigone, and a complete TUR. Treatment consisted of 40 Gy of external beam radiation concurrently with two cycles of cisplatin (20 mg/day for 5 days). Only three patients (7%) showed residual muscle-invasive disease at the time of partial cystectomy. At a median follow-up of 45 months, the 5-year OS and cancer-specific survival were both 100%. Whereas radical cystectomy remains the gold-standard therapy following neoadjuvant chemotherapy, resection of the primary tumor site with partial cystectomy has been used in partial and complete responders (Herr et al., 1998; Sternberg et al., 2003). Adjuvant chemotherapy has been reported to improve progression-free survival in patients with adverse pathologic features at the time of partial cystectomy (Kassouf et al., 2006); however, absolute numbers are small, warranting further studies to define the role of adjuvant therapy partial cystectomy.

Chemotherapy Monotherapy

The primary role for systemic chemotherapy in the treatment of muscle-invasive bladder cancer has been in the neoadjuvant or adjuvant setting in combination with radical cystectomy. Similar to radiation monotherapy, it is generally accepted that combination chemoradiation therapy is superior to chemotherapy alone. It is well established that an increased proportion of patients who receive neoadjuvant chemotherapy will have p0 disease at the time of cystectomy. Radical cystectomy remains the standard of care in patients who have had a complete response to neoadjuvant therapy; however, patients have refused cystectomy in this setting. The MSKCC group reported outcomes for 63 patients who declined cystectomy after achieving a complete response with neoadjuvant chemotherapy (Herr, 2008). At a minimum of 5 years of follow-up, 64% of patients were alive and 54% exhibited an intact bladder. Thirty-six percent of the cohort ultimately died of bladder cancer, of which the majority relapsed with invasive disease in the bladder. Predictors of prolonged survival with chemotherapy alone in this group included small solitary tumors and low-stage, completely resected tumors. Sternberg et al. (2003) also reported on the use of systemic MVAC and TUR with the intention of bladder preservation in 104 patients. Following completion of chemotherapy, patients underwent a repeat TUR, and 49% were noted to have a complete response. Sixty percent of patients were alive at a median follow-up of 56 months without further therapy. Patients downstaged to pT0 or to non–muscle-invasive disease exhibited superior survival compared with those who had persistent muscle-invasive disease. These data suggest that some patients with low-risk muscle-invasive tumors can be cured with TUR and chemotherapy alone; however, the risk for recurrence in the bladder remains significant, as evidenced by 46% of patients recurring in the bladder at a median time of 5.4 months in the Columbia cT0 series after neoadjuvant chemotherapy.

Prognostic Nomograms for Muscle-Invasive Bladder Cancer

As detailed earlier in this chapter, the TNM staging system provides valuable prognostic information following radical cystectomy. Despite its usefulness, there is often wide variation among patients with regard to absolute risk for recurrence as a result of the heterogeneity of tumor biology and patient characteristics. Better understanding and prediction of disease outcome is important to deliver appropriate adjuvant therapy and to counsel patients with regard to the risk for disease recurrence. The use of standard pathological data to predict outcomes was discussed earlier in this chapter. Nomograms have been developed in an effort to better predict the prognosis in patients with muscle-invasive disease (Bochner et al., 2006; Karakiewicz et al., 2006a; Shariat et al., 2006a). In addition to standard pathological features, molecular markers are now being incorporated into predictive models not only to improve prognostic accuracy, but also to provide the potential to predict response to therapy (Karam et al., 2007; Shariat et al., 2008, 2010; Youssef et al., 2009).

Nomograms incorporating clinical, pathologic, and molecular data have been developed as predictive tools in the muscle-invasive setting (Fig. 137.2). Two consortia have published easy-to-use nomograms for predicting recurrence following radical cystectomy. The International Bladder Cancer Consortium (IBCC) collected data on 9064 patients from 12 centers of excellence (Bochner et al., 2006). Significant variables in the nomogram included age, grade, pathologic stage, histologic subtype, lymph node metastasis, and timing of surgery. The final nomogram was significantly superior to standard prediction models in predicting disease-free survival following cystectomy (95% CI 0.75) compared with TNM stage (95% CI 0.68) or standard pathologic grouping models (95% CI 0.62). The authors modeled several lymph node variables including total number removed, number of positive nodes, and lymph node density, but found binary node status (positive vs. negative) to be the best predictor. The Bladder Cancer Research Consortium (BCRC) has also published a postcystectomy nomogram based on 728 patients from three centers (Karakiewicz et al., 2006a). As opposed to the IBCC nomogram, all patients in the BCRC had urothelial histology. Multivariate predictors of disease recurrence, cancer-specific mortality, and all-cause mortality at 2, 5, and 8 years postcystectomy included pT stage, nodal status, lymphovascular invasion, perioperative chemotherapy administration, and adjuvant radiation therapy. The nomogram improved predictive accuracy in favor of that of the AJCC staging system by 3.2% (0.748 vs. 0.780). Both nomograms have been validated in other patient cohorts (Zaak et al., 2010). More recently, the Cancer of the Bladder Risk Assessment (COBRA) score has been shown to be a relatively straightforward method of predicting mortality after radical cystectomy (Welty et al., 2017). Similar in concept to the CAPRA score for prostate cancer, this nomogram assigns clinical variables including age, tumor stage, and lymph node density a risk score, and it is relatively straightforward and easy to use compared with more complicated nomograms.

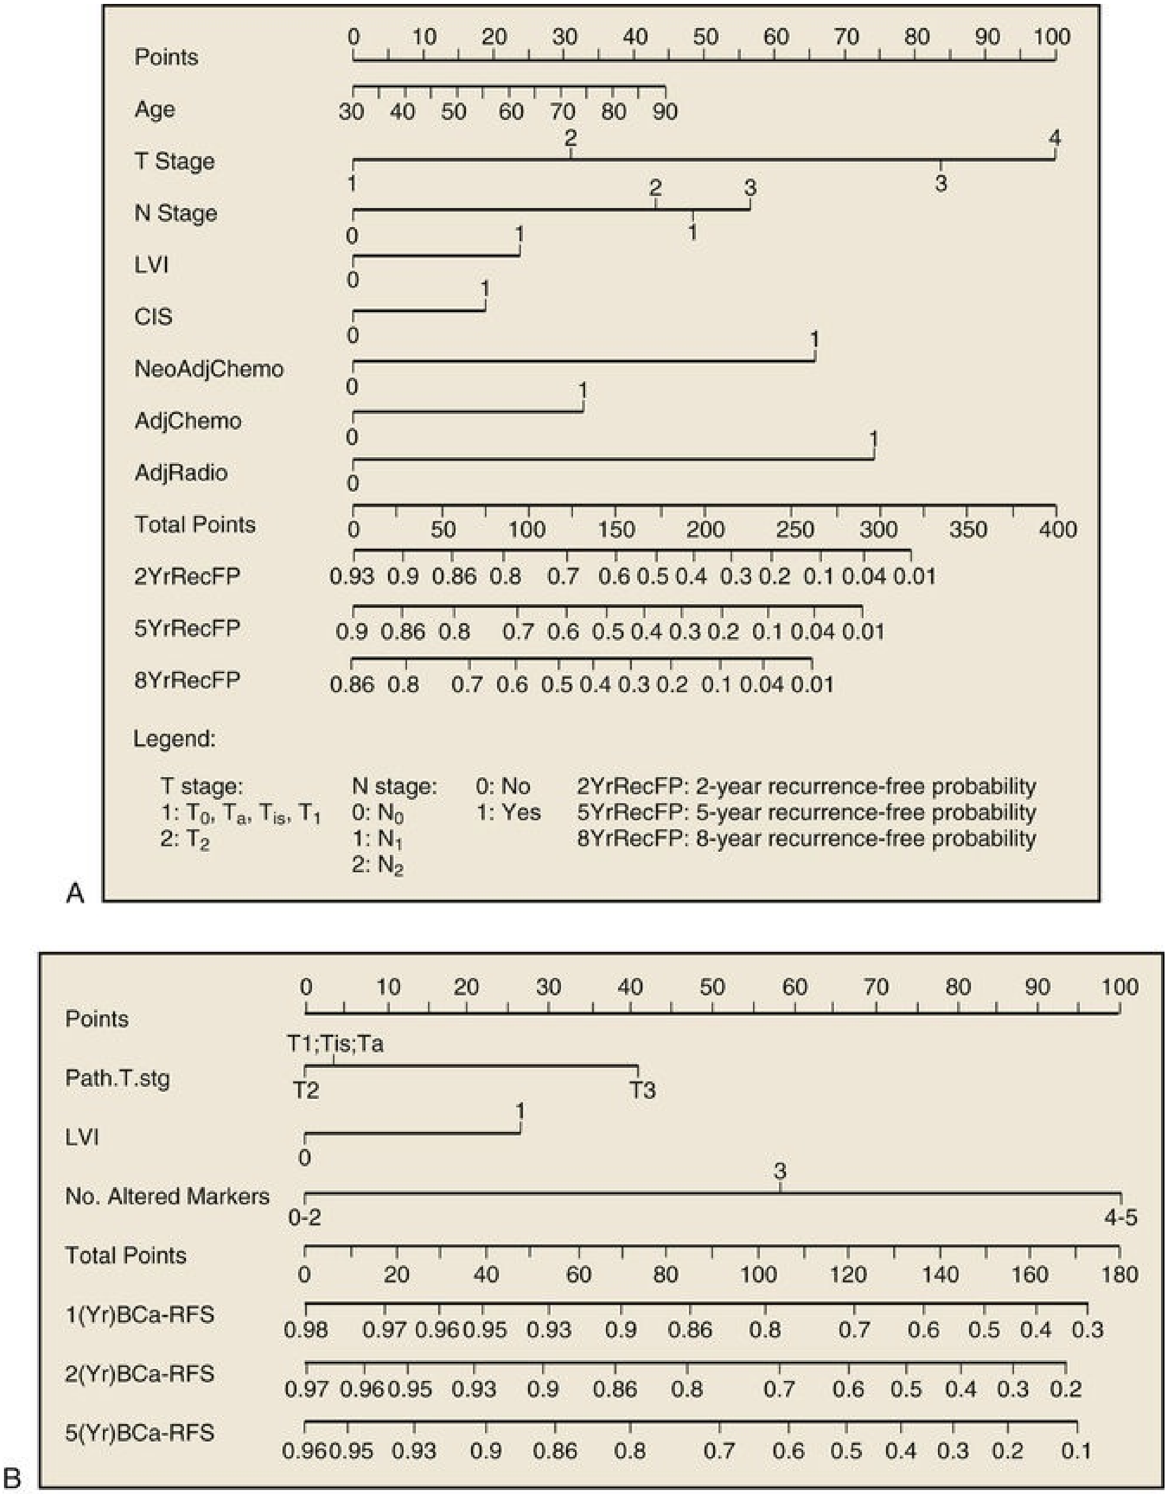

FIG. 137.2 To obtain nomogram-predicted probability of recurrence, locate patient values at each axis. Draw a vertical line to the "Point" axis to determine how many points are attributed for each variable value. Sum the points for all variables. Locate the sum on the *"Total Points"* line. Draw a vertical line toward the *2YrRecFP, 5YrRecFP,* and *8YrRecFP* axes to respectively determine the 2-year recurrence-free probability, 5-year

recurrence-free probability, and 8-year recurrence-free probability. (A) Postoperative nomogram for predicting recurrence after radical cystectomy. (B) Postoperative nomogram for predicting recurrence after radical cystectomy incorporating tissue biomarkers. *CIS,* Carcinoma in situ; *LVI,* lymphovascular invasion, *RFS,* recurrence-free survival. (A, From Karakiewicz PI, Shariat SF, Palapattu GS, et al. Nomogram for predicting disease recurrence after radical cystectomy for transitional cell carcinoma of the bladder. *J Urol* 176(4):1354–1362, 2006; B, from Shariat SF, Karakiewicz PI, Ashfaq R, et al. Multiple biomarkers improve prediction of bladder cancer recurrence and mortality in patients undergoing cystectomy. *Cancer* 112(2):315–325, 2008.)

Although postcystectomy nomograms provided enhanced prognostic value following treatment, precystectomy nomograms may include a greater impact in directing definitive therapy including neoadjuvant chemotherapy decisions. Using the same multicenter cystectomy cohort, Karakiewicz et al. (2006b) evaluated 726 patients and developed a nomogram incorporating age, TUR stage, tumor grade, and the presence of CIS. The multivariate nomogram was 75.7% accurate versus TUR stage (71.4%) in predicting non–organ-confined disease (pT3 or 4). The nomogram was also more accurate (63.1% vs. 61%) in predicting lymph node metastasis on final pathology. Although the overall performance characteristics of this nomogram did not dramatically improve the ability to predict non–organ-confined disease, it does demonstrate the usefulness and future potential of multivariable nomograms in the predictive setting. More recently, Lucca et al. (2016) reported on a preoperative nomogram incorporating the Glasgow prognostic score (a marker of systemic inflammation) with other known preoperative predictors of non–organ-confined disease in a population of patients with clinical N0M0 bladder cancer. Adding the inflammatory biomarker to the nomogram substantially improved its ability to predict non–organ-confined disease in this patient population. A nomogram has also been published to predict response rates to trimodal bladder preservation therapy (Coen et al., 2013). A cohort of 325 patients who underwent bladder preservation at a single institution was used in this evaluation. The final nomogram incorporated clinical T stage, presence of hydronephrosis, completeness of TUR, age, gender, and tumor grade. Using this nomogram, the ROC (receiver operating characteristic) curve was 0.69 for a complete response to therapy and 0.61 for bladder-intact disease-free survival.

Although nomograms appear to improve predictive accuracy over standard pathologic criteria, the addition of molecular markers has the potential to aid diagnostic accuracy further. Molecular markers are important in cell-cycle signaling and angiogenesis pathways, and their expression can be quantified by immunohistochemical staining. Inclusion of single biomarkers into prognostic nomograms is unlikely to significantly enhance the prognostic capability because of the complex tumor heterogeneity and biology. Shariat et al. (2008) studied the use of adding the molecular markers p53, pRB, p21, p27, and cyclin E1 into a nomogram. By adding the molecular markers, the nomogram improved predictive accuracy for recurrence and cancer-specific survival by 10.9% and 8.6%, respectively, for patients with pTa-3N0M0 bladder cancer following radical cystectomy. Shariat et al. (2012) also evaluated p53, p27, p21, and pRB in 272 cystectomy patients and in an external testing cohort of 52 patients with chemotherapy-naïve pT1-2N0M0 urothelial carcinoma. Overall, 80% of patients showed expression of at least one marker. The addition of the number of altered markers increased the accuracy of the base model for disease recurrence and cancer-specific mortality by 15.6% and 14.8%, respectively.

Nomograms, particularly those using novel molecular markers, have demonstrated improved predictive accuracy in favor of standard TNM factors alone. To date, these studies have been performed in retrospective cystectomy and bladder-sparing cohorts and require further validation in the prospective setting. Such nomograms provide the potential to aid clinicians in direct treatment both before definitive treatment (neoadjuvant chemotherapy vs. surgery) and after treatment (adjuvant therapy vs. surveillance).

Management of Metastatic Bladder Cancer

Systemic cisplatin-based combination chemotherapy is the standard of care for patients with metastatic urothelial bladder cancer. First-line systemic regimens include MVAC, HD-MVAC, and gemcitabine/cisplatin (Loehrer et al., 1992; Saxman et al., 1997; Sternberg et al., 1989, 2006b; von der Maase et al., 2005). Although the majority of patients with metastatic disease (40% to 70%) will experience an initial response to chemotherapy, most will ultimately progress with a median survival of 14 months and overall 5-year survival rates of 5% to 20% (Table 137.7) (Bellmunt et al., 2012; Saxman et al., 1997; Sternberg et al., 2006b; von der Maase et al., 2005). Despite the initial effectiveness of systemic cisplatin-based chemotherapy, there are several barriers to optimal delivery of chemotherapy in the bladder cancer population. Renal insufficiency is not uncommon in this population, limiting the use of cisplatin. Additionally, poor performance status, medical comorbidity, and frailty are often preexisting conditions that can limit a patient's ability to tolerate systemic therapy. A working group of medical oncologists has published criteria to define patients who are not cisplatin candidates, including any of the following: a World Health Organization or Eastern Cooperative Oncology Group performance status greater than 2, creatinine clearance less than 60 mL/min, grade 2 or above audiometric hearing loss, grade 2 or above peripheral neuropathy, or a New York Heart Association Class III or higher heart failure (Galsky et al., 2011). When cisplatin therapy is contraindicated, carboplatin has been substituted with the benefit of improved tolerability, but with the cost of decreased efficacy (Bellmunt et al., 1997; Dogliotti et al., 2007; Petrioli et al., 1996). Although carboplatin is a reasonable choice for patients in whom cisplatin is contraindicated, it should not be considered a first-line therapy for cisplatin candidates.

Poor performance status and the presence of visceral metastasis predict a poor response to chemotherapy for patients with locally advanced or metastatic urothelial carcinoma. The MSKCC group published their data on 203 patients with unresectable or metastatic bladder cancer treated with MVAC (Bajorin et al., 1999). They found a Karnofsky performance status of less than 80% and visceral (lung, liver, bone) metastasis to be independent predictors of poor outcome. Median survival times for patients who had zero, one, or two risk factors were 33, 13.4, and 9.3 months, respectively.

Randomized Trials in Metastatic Bladder Cancer

A phase III Intergroup randomized trial examined the effectiveness of MVAC therapy to that of single-agent cisplatin in patients with metastatic or locally advanced bladder cancer (Loehrer et al., 1992). A total of 269 patients were randomized, and those patients in the MVAC arm were noted to have significantly higher response rates (39% vs. 12%) and OS rates (12.5 vs. 8.2 months). Although superior in efficacy, the MVAC arm was more toxic with regard to leukopenia, mucositis, granulocytopenic fever, and drug-related mortality (3% to 4%). MVAC has also been compared with CISCA in patients with advanced urothelial carcinoma (Logothetis et al., 1990). In this study, 110 patients (86 bladder, 23 upper tract, 1 prostatic urethra) were randomized, with the MVAC regimen demonstrating improved response rates (65% vs. 46%) and OS (11.2 vs. 8.4 weeks) compared with CISCA.

Although most patients with metastatic urothelial carcinoma experience some response (complete or partial) to MVAC, the long-term survival rates are dismal (Bajorin et al., 1999; Saxman et al., 1997). In an effort to improve these results, Sternberg et al. (2001b) investigated whether increasing the dose intensity of MVAC with G-CSF could improve complete response rates and survival. In this study, 263 patients with chemotherapy-naïve metastatic or advanced urothelial carcinoma were randomized to HD-MVAC (MVAC + G-CSF; 2-week cycle) versus standard MVAC (4-week cycle). The HD-MVAC arm did achieve higher complete response rates (21% vs. 9%) and improved progression-free survival (9.1 vs. 8.2 months); however, OS was not significantly different between the two groups. Seven years later, additional follow-up was reported in this same cohort (Sternberg et al., 2006b). In the updated analysis, HD-MVAC was reported to have a statistically significant relative reduction in the risk for progression and death compared with that of MVAC (HR 0.76; 95% CI 0.58 to 0.99; $P = .042$).

Although MVAC has demonstrated efficacy in treating urothelial carcinoma, it has significant toxicity. The toxicity of MVAC led to trials of alternative less-toxic chemotherapy regimens. Most notably, a phase III randomized trial comparing gemcitabine/cisplatin to MVAC was conducted in 405 patients (von der Maase et al., 2000, 2005). There was no difference in response rates (49% vs. 46%), time to progression (7.4 vs. 7.4 months), and OS rates (13.8 vs. 14.8 months) between the two study arms. The updated study analysis confirmed equivalence of the two regimens (HR 1.09, 95% CI 0.88 to 1.34; $P = .66$). The gemcitabine/cisplatin regimen was better tolerated with only 37% of patients in that arm requiring dose modifications compared with 63% in the MVAC arm. Patients in the gemcitabine/cisplatin arm also experienced less grade 3–4 neutropenia, neutropenic fever, neutropenic sepsis, and mucositis. The toxicity-related death rate was also lower in the gemcitabine/cisplatin group (1% vs. 3%). Because of its equivalent efficacy and better tolerability, gemcitabine/cisplatin is the most widely used chemotherapeutic regimen for muscle-invasive and metastatic bladder cancer. The EORTC performed a phase II/III trial comparing gemcitabine/carboplatin versus methotrexate/carboplatin/vinblastine (MCAVI) for patients with metastatic urothelial carcinoma who were deemed "unfit" for cisplatin-based chemotherapy (DeSantis et al., 2012). These patients were considered "unfit" because of impaired renal function or poor performance status. Two hundred thirty eight patients were randomized to gemcitabine/carboplatin or MCAVI. Median OS was not significantly different between the two arms (9.3 months vs. 8.1 months; $P = 0.64$). However, severe toxicity was more common in the MCAVI arm.

Randomized trials have also assessed the usefulness of adding additional drugs to standard chemotherapy regimens (Bellmunt et al., 2000; von der Maase et al., 2006). The largest such trial was a phase III study that compared paclitaxel, gemcitabine, and cisplatin (PGC) to standard gemcitabine/cisplatin in 626 patients with locally advanced or metastatic urothelial cancer (Bellmunt et al., 2012). Overall response rates were significantly higher in the PGC arm (55.5% vs. 43.6%, $P = .0031$); however, there was no significant improvement in OS (15.8 vs. 12.7 months; HR 0.85; 95% CI 0.72 to 1.02, $P = .075$). There was also significantly more grade 3 and 4 neutropenia and thrombocytopenia in the PGC arm. A summary of the major chemotherapy trials for metastatic bladder cancer is presented in Table 137.7.

Second-Line Chemotherapy

There is no clear standard second-line chemotherapy for patients who progress or do not respond to first-line therapy. Patients who fail first-line chemotherapy have a dismal prognosis. Salvage chemotherapy in this setting with conventional agents typically has a suboptimal response rate (Albers et al., 2002; Dreicer et al., 1996; Lorusso et al., 1998; McCaffrey et al., 1997; Vaughn et al., 2002) (Table 137.8).

TABLE 137.8

Salvage Chemotherapy for Metastatic Urothelial Cancer

DRUG	AUTHOR (REFERENCE)	*N*	ELIGIBILITY	RR (%)	MEDIAN PFS (MONTHS)	MEDIAN OS (MONTHS)
Paclitaxel (24-hour)	Dreicer et al., 1996	9	One prior regimen	56	—	—
Paclitaxel (weekly)	Vaughn et al., 2002	31	One prior regimen for advanced disease, prior adjuvant chemotherapy and taxanes allowed	10	2.2	7.2
Docetaxel (every 3 weeks)	McCaffrey et al., 1997	30	One prior cisplatin regimen, prior taxanes not allowed	13	—	9.0
Gemcitabine	Lorusso et al., 1998	35	One prior platinum regimen	22.5	—	5.0

Gemcitabine-paclitaxel	Sternberg et al., 2001a	41	One prior cisplatin regimen including perioperative therapy	60	—	14.4

N, Number of patients; *OS,* overall survival; *PFS,* progression-free survival; *RR,* response rate.

Single-Agent Second-Line Chemotherapy

Multiple novel single agents have been evaluated in patients with advanced bladder cancer, typically with modest response rates of less than 20%.

Vinflunine is a novel antitubulin agent obtained from a vinca alkaloid (Culine et al., 2006). Bellmunt et al. (2009) compared vinflunine plus best supportive care versus best supportive care alone in patients with metastatic urothelial carcinoma previously treated with first-line platinum chemotherapy. Overall, 370 patients were randomized, with a 9% response rate in the vinflunine arm. At the time of initial publication, the results of the study met the 2.3-month improvement in OS (6.9 vs. 4.6 months); however, this did not achieve statistical significance. The authors published updated survival results in 2013, at which time OS had reached statistical significance in favor of the vinflunine arm (HR 0.719; 95% CI 0.570 to 0.906, $P = .0052$) (Bellmunt et al., 2013). Vinflunine is currently approved in Europe as a second-line agent for metastatic bladder cancer.

Paclitaxel has been evaluated in several small phase II studies with modest results. In a study of 31 patients with advanced or progressing urothelial cancer, who had previously been treated with at least one systemic chemotherapy, the patients were treated with a 1-hour weekly infusion of 80 mg/m^2 of paclitaxel. The median number of cycles delivered was three (one cycle = 4 weeks). Ten percent achieved a response, with a median OS time of 7.2 months (Vaughn et al., 2002). Two other phase II trials did not replicate the response rates (5% to 7%) with median survival times in the 6-month range (Joly et al., 2009; Papamichael et al., 1997). Docetaxel has also been used in a similar setting as a second-line agent. This regimen demonstrated modest response rates of 13% and median OS times of 9 months; however, 60% of patients developed myelosuppression requiring a dose reduction (McCaffrey et al., 1997).

Pemetrexed is a multitargeted antifolate agent. Initial phase II trials were promising, using 500 mg/m^2 of pemetrexed intravenously every 21 days and noting complete and partial response rates of 6.4% and 21%, respectively, in 47 patients. The median time to disease progression was 2.9 months, and median survival was 9.6 months (Sweeney et al., 2006). Grade 3 and 4 hematologic events were thrombocytopenia (8.5%, 0%), neutropenia (4.3%, 4.3%), and anemia (2.1%, 2.1%). However, a phase II trial using the same dose of pemetrexed showed less promising results in 13 patients with advanced disease who had previously received chemotherapy. In this cohort, only one (8%) patient had an objective response. Piritrexim is a synthetic antifolate agent that has also been investigated as a second-line agent. In a phase II trial of 27 patients with advanced, previously treated, urothelial carcinoma, piritrexim showed a 7% objective response rate. Toxicity was not insignificant with dose-limiting myelosuppression in 29% (Roth et al., 2002). Lassiter et al. (2008) obtained similar results in 23 previously treated patients in whom no objective responses were observed, and 2 patients had disease stabilization after two to four cycles.

Epothilones are nontaxane tubulin polymerization agents derived from fermentation of the myxobacteria *Sorangium cellulosum*. Ixabepilone is a semisynthetic analogue of natural epothilone B. In a phase II trial involving 45 patients with advanced urothelial carcinoma previously treated with either cisplatin or carboplatin-based chemotherapy, ixabepilone was reported to have an overall response rate of 12% and a median OS of 8 months. Unfortunately, the toxicity profile of this drug was significant, with 27% in the trial experiencing grade 4 toxicity in addition to one treatment-related death (Dreicer et al., 2007). Table 137.9 illustrates published single-agent studies in patients with relapsing or progressive disease following first-line chemotherapy.

TABLE 137.9

Salvage Trials With Single-Agent Chemotherapeutic and Novel Agents for Metastatic Urothelial Cancer

---

AGENT	AUTHOR	*N*	PRIOR	RR (%)	MEDIAN PFS (MONTHS)	MEDIAN OS (MONTHS)
Gemcitabine	Lorusso et al., 1998	35	One prior platinum regimen	23	3.8	5

N, Number of patients; *OS,* overall survival; *PFS,* progression-free survival; *RR,* response rate.

Multiagent Second-Line Chemotherapy

For patients who progress following treatment with gemcitabine/cisplatin, second-line MVAC may be an option for select patients. Han et al. (2008) reported on a small cohort (*N* = 30) of patients who were treated with MVAC after failing initial therapy with gemcitabine/cisplatin. The overall response rate was 30%, and 6.7% of patients achieved a complete response. Patients who previously had a response to gemcitabine/cisplatin had a 44% response rate compared with a 14% response rate in patients who had not responded to initial therapy.

Multiple studies have investigated the effectiveness of paclitaxel and gemcitabine as a second-line agent. The published response rates of these trials vary widely from 0% to 60%, likely reflecting different dosing and administration schedules (Albers et al., 2011; Kanai et al., 2008; Meluch et al., 2001; Sternberg et al., 2001a). The largest of these trials randomized 102 patients to a temporary six-cycle course of paclitaxel and gemcitabine compared with prolonged treatment with gemcitabine/paclitaxel. Although there was no significant difference in OS or progression-free survival between the two groups, the objective response rates were 37.5% and 41.5%, respectively (Albers et al., 2011).

Larotaxel is a next-generation semisynthetic taxane that includes a mechanism of action similar to that of docetaxel and paclitaxel. Larotaxel has been postulated to have advantages beyond other taxanes including activating taxane-resistant tumor cells and the ability to cross the blood-brain barrier (Metzger-Filho et al., 2009; Sessa et al., 2002). In a phase III randomized trial, larotaxel/cisplatin combination therapy was compared with gemcitabine/cisplatin as first-line treatment for locally advanced or metastatic urothelial carcinoma in 337 patients (Sternberg et al., 2013). The trial was closed early as a result of the sponsor's decision to stop clinical development of larotaxel. At the time of analysis, there was no difference in OS between the two study arms, and progression-free survival was poorer with larotaxel/cisplatin (5.6 vs. 7.6 months), suggesting that this regimen does not improve outcomes compared with standard gemcitabine/cisplatin.

There is no general consensus regarding the optimal second-line multiagent therapy for patients with progressing and/or metastatic urothelial carcinoma.

Immune Checkpoint Inhibitor Therapy

Given the suboptimal results of second-line chemotherapy in metastatic urothelial carcinoma, there has been a desperate need for the development of effective novel agents in this disease. As noted earlier, immunotherapy has an established track record in the treatment of non–muscle-invasive bladder cancer. Recently, the development of immune checkpoint inhibitor therapy has been a significant advance in this disease.

Inhibitory immune checkpoint molecules are expressed on the surface of both T cells and tumor cells. Activated T cells express cytotoxic T lymphocyte–associated antigen 4 (CTLA-4), an immune checkpoint molecule that interacts with receptors on the surface of antigen-presenting cells to inhibit T-cell proliferation. Ipilimumab and tremelimumab are monoclonal antibodies that bind to CTLA-4. Programmed cell death-1 (PD-1) is a molecule expressed on activated T cells that binds to PD-L1 to modulate the immune response. Tumor cells may express PD-L1 as a mechanism to neutralize T-cell activation. Atezolizumab, durvalumab, and avelumab are monoclonal antibodies that bind to PD-L1. Pembrolizumab, and nivolumab are monoclonal antibodies that bind to PD-1. These immune checkpoint inhibitors result in an increase in T-cell activation and proliferation, which may result in an antitumor response.

Second-Line Immune Checkpoint Inhibitor Therapy

Immune checkpoint inhibitors have now been studied extensively in metastatic urothelial carcinoma previously treated with platinum-based chemotherapy. Several single-arm trials have investigated PD L1 inhibitors. The IMvigor 210 study is a phase II trial of atezolizumab 1200 mg intravenously every 3 weeks in patients with metastatic urothelial carcinoma with progression after prior platinum-based chemotherapy (Rosenberg et al., 2016). In this trial, 310 eligible patients received treatment. PD-L1 expression on infiltrating immune cells was defined by the percentage of PD L1–positive immune cells into three groups (IC0 <1%; IC1 ≥1% but <5%; IC2/3 ≥5%). The primary analysis demonstrated that compared with a historical chemotherapy control, overall response rate of 10%, atezolizumab resulted in a significantly improved objective response rate in each prespecified immune cell group and all patients (15% [95% CI 11 to 20], $P = 0.0058$). With a median follow-up of 11.7 months, 38 of 45 responders demonstrated ongoing response to therapy. Grade 3-4 treatment-related adverse events occurred in 16% of treated patients. Grade 3-4 immune-mediated adverse events occurred in 5% of treated patients.

In an open-label phase I/II study, 191 patients with previously treated metastatic urothelial carcinoma were treated with durvalumab 10 mg/kg intravenously every 2 weeks (Powles et al., 2017b). The objective response rate was 17.8% (95% CI 12.7% to 24.0%), including 7 complete responses. Responses were observed regardless of expression of PD-L1. Median progression-free survival was 1.5 months, and median OS was 18.2 months. Grade 3–4 treatment-related adverse events occurred in 6.8% of patients.

In the JAVELIN Solid Tumor study, 249 patients previously treated with platinum-based chemotherapy received avelumab 10 mg/kg every 2 weeks (Patel et al., 2018). In 161 patients with at least 6 months of follow-up, the overall response rate was 17% (95% CI 11% to 24%). Grade 3–4 treatment-related adverse events occurred in 8%.

KEYNOTE-012 was an open-label phase Ib basket trial of the anti–PD-1 agent pembrolizumab (Plimack et al., 2018). In the urothelial cohort, 33 patients with tumors that expressed PD-L1 received pembrolizumab 10 mg/kg intravenously every 2 weeks. Fifteen percent of patients experienced grade 3 treatment-related adverse events. In addition, 26% of assessable patients demonstrated objective response including 11% with complete responses.

In CheckMate 275, 270 patients with metastatic urothelial carcinoma previously treated with platinum-based chemotherapy received nivolumab 3 mg/kg intravenously every 2 weeks (Sharma et al., 2017). An objective response rate of 19.6% was demonstrated. Grade 3–4 treatment-related adverse events occurred in 18% of patients.

Based on the promising phase I and II results of immune checkpoint inhibitor therapy, two phase III trials have been conducted in the second-line setting. These trials deserve a more detailed discussion. IMvigor211 is a randomized phase III trial in patients with metastatic urothelial carcinoma who had received two or more previous lines of chemotherapy and had progressed following one or more platinum-containing regimens (for metastatic disease or in a neoadjuvant/adjuvant setting) (Powles et al., 2017a). The investigators randomized 931 patients to receive either atezolizumab ($N = 467$) or investigator's choice of chemotherapy, which could include either dicetaxel, paclitaxrel, or vinflunine ($N = 464$). Patients were stratified into three cohorts based on PD-L1 expression on archival tumor: IC0 (<1%), IC1 (1% to 5%), or IC2–3 (≥5%). The primary endpoint was OS in prespecified populations: IC2–3, IC1–3, intention-to-treat. In the IC2–3 group, OS for the atezolizumab group and for the chemotherapy group was 11.1 months and 10.6 months, respectively; stratified HR 0.87, 95% CI 0.6 to 1.21, $P = 0.41$. Thus, the study did not meet its primary endpoint for efficacy.

KEYNOTE 45 was a phase III randomized trial with a similar study design as IMvigor211 (Bellmunt et al., 2017). Five hundred forty-two patients with advanced urothelial carcinoma that recurred or progressed after platinum-based chemotherapy were randomized to pembrolizumab 200 mg intravenously every 3 weeks or investigator's choice of chemotherapy, again paclitaxel, docetaxel, or vinflunine. This study had coprimary endpoints, OS, and progression-free survival in all patients, and the PD-L1 score (percentage of PD-L1–expressing tumor and infiltrating immune cells) was greater than or equal to 10% among patients with a tumor. The median OS for the entire group was 10.3 months for pembrolizumab versus 7.4 months for chemotherapy, resulting in a HR for death of 0.73; 95% CI 0.59 to 0.91; $P = 0.002$. The median OS among the PD-L1 greater than 10% patients was also superior for pembrolizumab (8 months vs. 5.2 months; $P = 0.005$). There was no significant difference in progression-free survival among either all patients or those in the PD-L1 greater than 10% group. Fewer treatment-related adverse events were noted in the pembrolizumab group compared with the chemotherapy group. On the basis of this trial, pembrolizumab has now received full US Food and Drug Administration (FDA) approval for the treatment of patients with metastatic urothelial carcinoma previously treated with platinum-based chemotherapy.

First-Line Immune Checkpoint Inhibitor Therapy in Cisplatin-Ineligible Patients

The immune checkpoint inhibitors have also been studied in the first-line setting for patients with advanced or metastatic urothelial carcinoma who are cisplatin-ineligible. In IMvigor210, 119 patients received atezolizumab 1200 mg intravenously every 21 days (Balar et al., 2017b). The objective response rate and complete response rate were 23% and 9%, respectively. Median OS was 15.9 months. This compares favorably with what has been previously demonstrated with carboplatin-based chemotherapy.

In KEYNOTE-052, 370 cisplatin-ineligible patients were treated with pembrolizumab 200 mg intravenously every 3 weeks (Balar et al., 2017a). Twenty four percent of patients demonstrated an objective response, and at the time of data cutoff, 83% of these responses were ongoing. This also compares favorably with previously reported carboplatin-based therapy. Based on these two trials, the FDA has approved both atezolizumab and pembrolizumab for first-line treatment of cisplatin-ineligible patients with advanced urothelial carcinoma.

FDA-Approved Agents and Future Directions

The unprecedented activity of the immune checkpoint inhibitors in metastatic urothelial carcinoma has resulted in FDA approval of five agents. The anti-PD-L1 agents atezolizumab, durvalumab, and avelumab received approval in patients with metastatic urothelial cancer previously treated with platinum-based chemotherapy. The anti-PD-1 agents pembrolizumab and nivolumab received approval in patients with metastatic urothelial cancer previously treated with platinum-based chemotherapy. In addition, atezolizumab and pembrolizumab are approved for first-line treatment of patients with metastatic urothelial carcinoma who are not candidates for cisplatin-based chemotherapy regimens.

The continued development of immune checkpoint inhibitor therapy in urothelial carcinoma is clearly warranted. Ongoing trials include combining an immune checkpoint inhibitor with cytotoxic chemotherapy in the first-line setting, evaluation of immune checkpoint inhibitors in the adjuvant setting for postcystectomy high-risk patients, and evaluation in bacille Calmette-Guérin (BCG) refractory non–muscle-invasive bladder cancer.

Targeted Therapy

Vascular Endothelial Growth Factor Inhibitor Therapy

Vascular endothelial growth factor (VEGF) receptors are expressed in urothelial carcinomas (von Hardenberg et al., 2014). It is well established that VEGF recruits circulating endothelial progenitors, which are critical for angiogenesis, which is essential for tumor growth and metastatic spread (Carmeliet and Jain, 2000). VEGF expression in both urine and blood has been shown to correlate with metastatic potential and disease recurrence (Crew et al., 1999; Fauconnet et al., 2009). Bevacizumab is a humanized monoclonal antibody of VEGF. Bevacizumab has been evaluated in patients with advanced urothelial carcinoma. In a phase II trial by the Hossier Oncology Group, 43 chemotherapy-naïve patients with either metastatic or unresectable urothelial carcinoma received bevacizumab in combination with gemcitabine/cisplatin (Hahn et al., 2011). The overall response rate in this cohort was 72% (19% complete, 53% partial). With a median follow-up of 27 months, median progression-free survival was 8.2 months, and median OS was 19.1 months. Of note, grade 3 to 4 hematologic toxicity was not insignificant, with neutropenia in 35%, thrombocytopenia in 12%, anemia in 12%, and neutropenic fever in 2%. Three treatment-related deaths were also reported. The results of a phase III intergroup study that aims to define further the role of bevacizumab in combination with gemcitabine/cisplatin in patients with advanced urothelial carcinoma is forthcoming.

Sunitinib is an oral inhibitor of multiple tyrosine kinases, including VEGF receptors. Sunitinib has demonstrated antitumor activity in human bladder cancer models (Sonpavde et al., 2009; Yoon et al., 2011). Sunitinib was reported as demonstrating a partial response in 8% and disease stabilization in 54% of 37 ciplatin-ineligible patients with advanced urothelial carcinoma (Bellmunt et al., 2011). The median progression-free survival was 5.9 months. Much like bevacizumab, sunitinib has been trialed in combination with gemcitabine/cisplatin, but the side-effect profile was unsatisfactory (Galsky et al., 2013). Sunitinib was also studied in a randomized, phase II trial of maintenance therapy following an initial response to standard chemotherapy compared with placebo (Grivas et al., 2014). The study did not achieve the predefined power as a result of poor accrual and premature closure; however, the maintenance sunitinib arm did not improve 6-month progression-free survival rates (2.9 vs. 2.7 months, respectively). Sorafenib, a similar multikinase inhibitor, has been studied in combination with gemcitabine/cisplatin but did not demonstrate superiority compared with chemotherapy alone (Krege et al., 2014).

Epidermal Growth Factor Receptor Therapy

Epidermal growth factor receptor (EGFR) has demonstrated overexpression in bladder tumors, and the extent of expression has also correlated with stage and grade of tumors (Neal et al., 1990). Cetuximab is a monoclonal antibody to EGFR, and it has been approved for colorectal carcinoma. Cetuximab has been studied in the phase II setting in patients with metastatic urothelial cancer who received previous chemotherapy (Wong et al., 2012). A total of 39 patients were randomized to cetuximab with or without paclitaxel. The single-agent cetuximab arm closed after 9 of 11 patients progressed by 8 weeks. Cetuximab did appear to augment the activity of the paclitaxel arm, with an overall response rate of 28.5% and a median progression-free survival of 115 days. Cetuximab has also been evaluated in combination with gemcitabine/cisplatin in the phase II setting, but did not improve OS (Pea, 2012). The oral tyrosine kinase inhibitor (TKI) gefitinib has produced disappointing results today in urothelial carcinoma trials. In a phase II trial of 31 patients with metastatic urothelial carcinoma, gefitinib was largely ineffective, with a median progression-free survival of 2 months; only two patients survived with no disease progression past 6 months (Petrylak et al., 2010). Gefitinib has also been evaluated in combination with gemcitabine/cisplatin and did not improve response rate compared with that of historical controls (Philips et al., 2009). Gefitinib is also being evaluated as maintenance therapy following systemic chemotherapy; however, the results from such studies have not been reported.

Trastuzumab, an anti–Her-2 monoclonal antibody, has been evaluated in several studies. Human epidermal growth factor receptor 2 (HER2)/neu expression in urothelial cancers is variable and may predict a more aggressive phenotype. In 44 patients with HER2/neu–positive tumors, the overall response rate was 70% when combined with paclitaxel, gemcitabine, and carboplatin (Hussain et al., 2007). A large randomized phase II trial compared gemcitabine/platinum with or without trastuzumab. No difference in progression-free survival, overall response rate, or OS was demonstrated by the addition of trastuzumab (Oudard et al., 2015).

Laptinib is an oral TKI that targets both EGFR and HER2. A phase II trial of lapatinib in 59 patients whose disease progressed on platinum-based chemotherapy demonstrated disease stabilization in 31% of evaluable patients (Wülfing et al., 2009). The median time to disease progression and OS was 8.6

weeks and 17.9 weeks, respectively. The median survival was significantly improved in patients whose tumors expressed EGFR and/or HER2. A recently reported phase III trial randomized 232 patients with HER1- or HER2-positive disease who had received first-line chemotherapy to maintenance lapatinib versus placebo. Unfortunately, this study did not demonstrate benefit of maintenance lapatinib compared with placebo (Powles et al., 2017a).

Fibroblast Growth Factor Receptor Therapy

FGFR3 mutations are commonly seen in low-grade noninvasive papillary bladder cancer. In papillary muscle-invasive bladder cancer, *FGFR3* mutations occur much less frequently. If *FGFR3* mutations are present, these can be targeted using FGFR TKIs. BGJ398 is an FGFR 1 to 3 TKI. In the phase I dose-escalation study of this agent, 3 partial responses were noted in 8 patients with FGFR3-mutated bladder cancer treated at dose levels considered therapeutic (Nogova et al., 2017). Based on these promising results, a phase II study of this agent in FGF3-mutated metastatic urothelial carcinoma has been completed, and the results are forthcoming. Other FGFR-3 TKIs are also under investigation in urothelial cancer.

Key Points

- Optimal treatment of muscle-invasive bladder cancer requires a multidisciplinary approach incorporating urologic oncologists, medical oncologists, and radiation oncologists. Current clinical staging modalities lack the sensitivity and specificity to predict accurately the final disease stage, which is currently a major limitation to pretreatment decision making.
- The gold standard therapy for organ-confined muscle-invasive bladder cancer is radical cystectomy with neoadjuvant cisplatin-based chemotherapy.
- Bladder preservation with chemoradiation therapy has become an increasingly popular option in the muscle-invasive setting and has demonstrated outcomes comparable to those of radical cystectomy in highly selected patients.
- Despite aggressive surgical therapy, approximately 50% of cystectomy

patients will ultimately die of disease.

- Meta-analysis from systemic cisplatin-based neoadjuvant chemotherapy trials has demonstrated a modest but statistically significant survival advantage. The evidence for adjuvant chemotherapy is less robust secondary to inadequately powered trials and methodologic flaws.
- Initial response rates with cisplatin-based chemotherapy in the metastatic setting are favorable; however, durable responses are rare, and outcomes for this patient population are dismal.
- Multiple new second-line chemotherapy trials have been completed or are under way with varying response rates. Newer biologic agents hold promise; however, evidence is currently lacking, and more studies are warranted.

Surgical Management of Bladder Cancer

Transurethral, Open, and Robotic

Neema Navai MD, Colin P.N. Dinney MD

According to data available from the American Cancer Society, in 2018 there were expected to be an estimated 81,190 new cases and 17,240 deaths from bladder cancer in the United States (Noone et al., 2018). **This ranks bladder cancer as one of the most common noncutaneous malignancies in the United States.** Without appropriate surgical therapy, the disease can be deadly and can impart significant health care costs. Surgical therapy, whether for non–muscle-invasive or muscle-invasive disease, requires careful attention to technique, oncologic principles, and a firm understanding of disease pathogenesis.

During the initial evaluation, not only does **transurethral resection (TUR) help to establish the pathological diagnosis and the local extent of the disease but should be viewed as a complete oncologic procedure, especially in the setting of low-grade and non–muscle-invasive tumors.** However, in the setting of a muscle-invasive tumor, to achieve adequate local control and to maximize the chance for cure, radical cystectomy with a regional lymph node dissection is necessary.

The history of TUR and surgical removal of the bladder dates to the 1800s. Bardenheuer of Germany is credited with performing the first cystectomy in 1887 in a patient with an advanced tumor of the bladder (Stenzl et al., 2005). Around that same time the first modern endoscope was invented through collaboration between Maximilian Carl-Friedrich Nitze and Joseph Leiter. Nitze, another German urologist, and Leiter, an instrument maker, created a tool that would evolve into the modern instrumentation used today.

The first modern technique for radical cystectomy appeared in 1956 from

Paquin and Marshall. In their early description, radical cystectomy in men began with a perineal exploration and dissection of the rectum from the bladder and prostate under direct visualization. In addition, they favored cutaneous ureterostomies for urinary diversion (Paquin and Marshall, 1956). The initial report by Whitmore and Marshall (1956) of surgical outcomes in 100 patients in that same year demonstrated significant morbidity and 17 (17%) postoperative deaths. Refinements during the years have resulted in substantial improvements in oncologic outcomes and surgical morbidity. A more contemporary analysis of 1142 patients demonstrated only a 0.9% inpatient mortality rate and a 2.7% 90-day mortality rate after radical cystectomy (Shabsigh et al., 2009).

Oncologic outcomes have similarly improved from the 21% to 49% 5-year survival rate reported by Whitmore and Marshall in 1962 to a 59% 5-year survival rate in a study of 507 patients (Madersbacher et al., 2003) and 66% in the largest report to date of 1054 patients treated at the University of Southern California. In addition to improvements in surgical technique, **the administration of neoadjuvant chemotherapy has been demonstrated to improve survival from a median of 46 months to 77 months** (Grossman et al., 2003) **and should be considered in all patients with muscle-invasive tumors who are scheduled to undergo radical cystectomy.** The landscape of systemic therapy for bladder cancer is rapidly changing with the addition of immuno-oncologic therapies for bladder cancer. We anticipate changes to the paradigm of treatment in the coming years, including early stage disease. In addition, further refinements in patient selection and the use of molecular profiling are likely to enter into the decision process in the management of bladder cancer patients. It goes without saying that any clinician managing bladder cancer patients needs to stay diligent and up to date in regard to these developments.

Transurethral Resection of Bladder Tumors

Advances in operative instrumentation have greatly enhanced the ability of urologists to identify, treat, and follow patients with bladder tumors. The approach to a new patient with a bladder tumor mirrors that of any new patient visit, with particular attention paid to those factors most likely to have contributed to the development of bladder cancer. A detailed history and physical examination should be performed. Care should be taken to identify known risk factors including but not limited to tobacco exposure, previous cyclophosphamide chemotherapy, aromatic amines, and phenacetin use. Information regarding surgical implants and valvular heart disease may influence antibiotic prophylaxis and should be obtained and compared with current guidelines. In addition, all patients should be queried regarding either a personal or a family history of bleeding with procedures and the use of anticoagulants, because these questions are relevant in preparation for surgery. We have not observed significant bleeding difficulty in patients who are on aspirin, and it is not our routine to stop aspirin therapy; however, we advise caution in patients taking other anticoagulants (e.g., warfarin, heparin, clopidogrel, ticagrelor, prasugrel) because these pose a higher bleeding risk. The specific timing of discontinuation as it relates to each medication's half-life and the need for bridging should be discussed preoperatively with the appropriate care team.

Physical examination should be thorough and include palpation of abdomen in the suprapubic region noting any palpable mass. A digital rectal examination (DRE) in men can be informative and may aid if there is a suspicion for prostatic involvement. Likewise a bimanual examination in women can elucidate anterior vaginal involvement. Routine laboratory studies should be obtained and include a complete blood count, metabolic panel, coagulation panel, and urinalysis with culture. In the setting of active infection, resection should be delayed until clearance of bacteria with appropriate therapy.

Upper tract imaging should be obtained to complete the diagnostic evaluation and this can include renal ultrasound in conjunction with retrograde pyelogram, computed tomography (CT) urogram (CTU), magnetic resonance imaging (MRI), and rarely intravenous pyelogram. Care should be taken to ensure adequate renal function (glomerular filtration rate

[GFR] > 60 mL/min) if intravenous iodinated contrast is being considered. As an alternative, MRI contrast agents can be administered for GFR greater than 30 mL/min, but these are contraindicated for those less than 30 mL/min. In the case of muscle-invasive tumors, formal staging evaluation should be obtained inclusive of the chest, abdomen, and pelvis.

Patients will routinely have first undergone cystoscopy in the office with a flexible cystoscopy, allowing for visual confirmation of a mucosal tumor and aiding in surgical planning. At the time of diagnostic cystoscopy, care should be taken to note the location and extent of tumor burden.

Although experienced clinicians have been known to predict accurately the stage and grade of tumors on follow-up cystoscopy (Herr et al., 2002), adequate tissue sampling must be obtained at baseline even when a low-grade tumor is suspected. In the setting of tumors overlying a ureteral orifice, clinicians should be prepared to perform additional interventions including ureteroscopy and ureteral stent placement, and they may require the use of fluoroscopy at the time of TUR.

TUR of bladder tumors is performed with the aid of a rigid cystoscope. To ensure adequate maneuverability the patient should be positioned in dorsal lithotomy. Based largely on an extrapolation from a randomized study examining antibiotic prophylaxis for TUR of the prostate in 400 patients, which showed a reduction in postoperative bacteriuria (Wagenlehner et al., 2005), **the American Urologic Association recommends the routine use of antibiotic prophylaxis for patients undergoing TUR of bladder tumors**, and it should be administered within 1 hour of the procedure. **As of July 2016 the US Food and Drug Administration (FDA) changed the label for fluoroquinolone antibiotics. This warning cautioned against the use of this class of antibiotics for conditions such as uncomplicated urinary tract infections, and, although no specific statement was made regarding their use as prophylactic antibiotics, we advise alternate classes of antibiotics be used whenever possible.**

A thorough visual inspection is then performed using the 30-degree lens to examine the urethra in its entirety and then to perform a preliminary evaluation of the bladder mucosa and ureteral orifices. A visual obturator should be used to minimize trauma to the urethra during this phase. After initial inspection, a 70-degree lens should be used to completely evaluate the bladder again with particular attention paid to the bladder neck, dome, and anterior wall. If necessary a more acute lens such as a 120-degree can be used if full visualization is not possible otherwise. The location and extent of tumors should be noted.

Resection can then be performed with either monopolar or bipolar electrocautery. Irrigation fluid can either be sterile water or 1.5% glycine in the case of monopolar electrocautery or 0.9% sodium chloride if bipolar current is used. This has the added benefit of lowering the risk of postoperative electrolyte abnormalities as well as mitigating an obturator reflex if the tumor is overlying the lateral walls of the bladder.

The goal of any resection should be the visual eradication of any tumor burden and the assurance of an adequate depth of resection. Using cutting current, a loop electrode is used to resect the tumor inclusive of muscularis propria (Fig. 138.1). Histologically, bladder tumors frequently exhibit growth beyond the visible edge and, as such, resection should include an approximate 2-cm margin of normal-appearing tissue. Wide resection of tumors ensures completeness whether the tumor has a broad base or a tentacular growth pattern (Fig. 138.2). After resection to visual completion, the bladder should be emptied and a bimanual examination under anesthesia (EUA) performed. Accordingly, any palpable lesion should be noted and staged clinically (cT3b). **In addition, the American Urologic Association and Society of Urology Oncology joint guideline statement recommends enhanced cystoscopic techniques such as narrow band imaging and blue light cystoscopy whenever possible.** These techniques have been shown to increase tumor detection and decrease recurrence rates

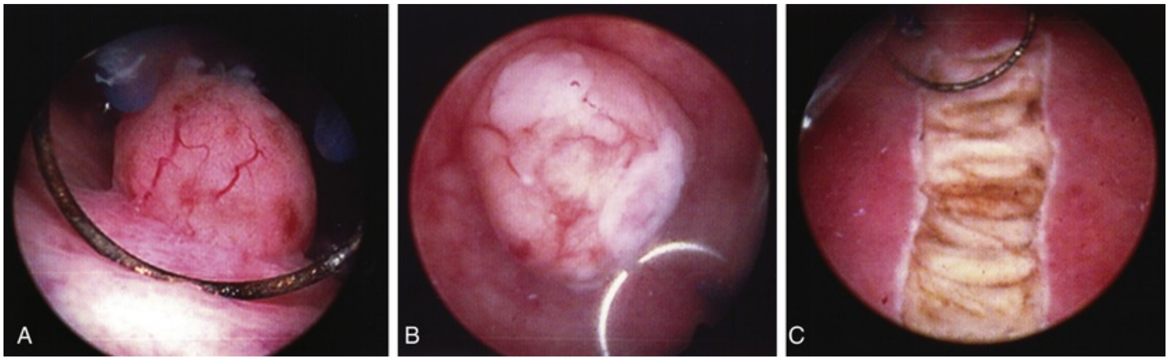

FIG. 138.1 (A) Broad-based papillary lesion. (B**)** Resection of lesion with loop electrocautery. (C) Depth of resection to detrusor muscle.

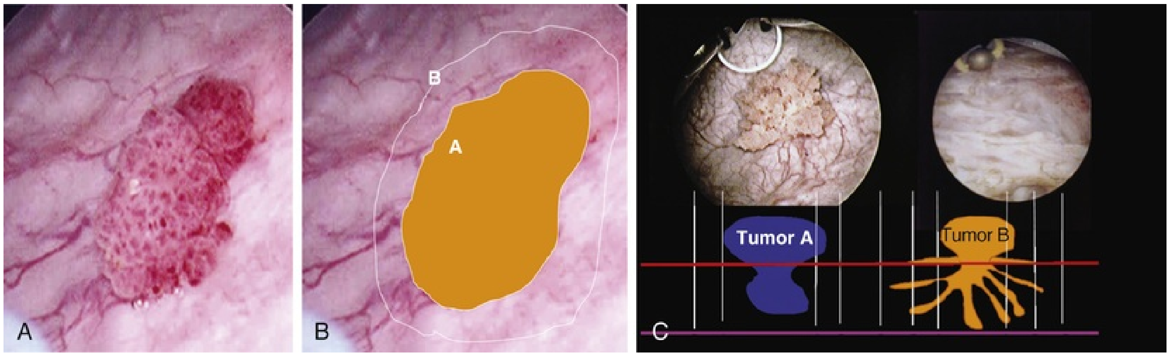

FIG. 138.2 (A) Papillary bladder lesion. (B) Visual boundary of tumor *(A)* and margin of resection to optimize tumor destruction *(B).* (C) Deep invasion of tumor in broad-based and tentacular pattern.

Tumors may pose specific challenges, and a proper understanding of technique helps minimize the risk of complications. When tumors are encountered on the lateral wall, there is the risk of an obturator reflex whereby the cautery current stimulates the obturator nerve, causing the ipsilateral leg to adduct. This can lead to inadvertent deflection of the instrument laterally and can cause perforation. To lessen this risk, we recommend the following techniques. First, minimize distention of the bladder to the minimum needed to perform the resection. Second, check whether available bipolar cautery may mitigate or eliminate the reflex. Last, if the patient is under a general anesthetic, muscle relaxant can be administered, thereby lessening any movement resulting from obturator nerve stimulation.

Tumors overlying a ureteral orifice pose another challenge. In this setting, only pure cutting current should be used, and resection strokes should be as quick as possible to minimize the possibility of cauterizing the ureteral orifice closed. **Data suggest routine stenting is not necessary after ureteral orifice resection.** Mano et al. (2012) found that of 79 patients in whom a ureteral orifice was resected, only 3 (4%) developed hydronephrosis. Although this retrospective study would suggest stenting is not needed in the case of large resections and extensive cautery, we would suggest that stenting may be useful in the short term, although it may not affect ultimate stricture rates. Finally, tumors located at the dome of the bladder may be difficult to resect because of angulation, distance, and concern for intraperitoneal perforation. The challenges are multifactorial and in some cases difficult to overcome. Minimizing bladder distention and suprapubic pressure, either with your nondominant hand or with that of an assistant, can help maneuver the bladder tumor into a location more amenable to resection. A straight ahead loop can also be employed. Care should be observed to avoid prolonged cautery because transmission of heat/energy could potentially occur to adjacent bowel viscera even in the absence of bladder perforation.

Perforation of the bladder may be the natural result of an adequate resection, especially in the setting of advanced tumors (Fig. 138.3). Whereas posterior tumors and those of the dome may result in an intraperitoneal perforation (see Fig. 138.3B), resections elsewhere in the bladder are more likely to result in an extraperitoneal perforation (see Fig. 138.3A). In the event of an extraperitoneal perforation, treatment consists of Foley catheter drainage and observation. However, **large intraperitoneal perforations, although rare, with an incidence of 0.36% in a study of 4144 TURs** (Golan et al., 2010)**, can lead to significant morbidity.** Findings during resection suggestive of an intraperitoneal rupture include loss of bladder distention, visualization of a defect posteriorly or at the dome, and palpable distention of the abdomen. When suspected, confirmation can be obtained with a cystogram at the same setting. In the presence of an intraperitoneal rupture, treatment consists of abdominal exploration, meticulous inspection of the bowel, and repair of the injury with a Foley catheter and abdominal drainage.

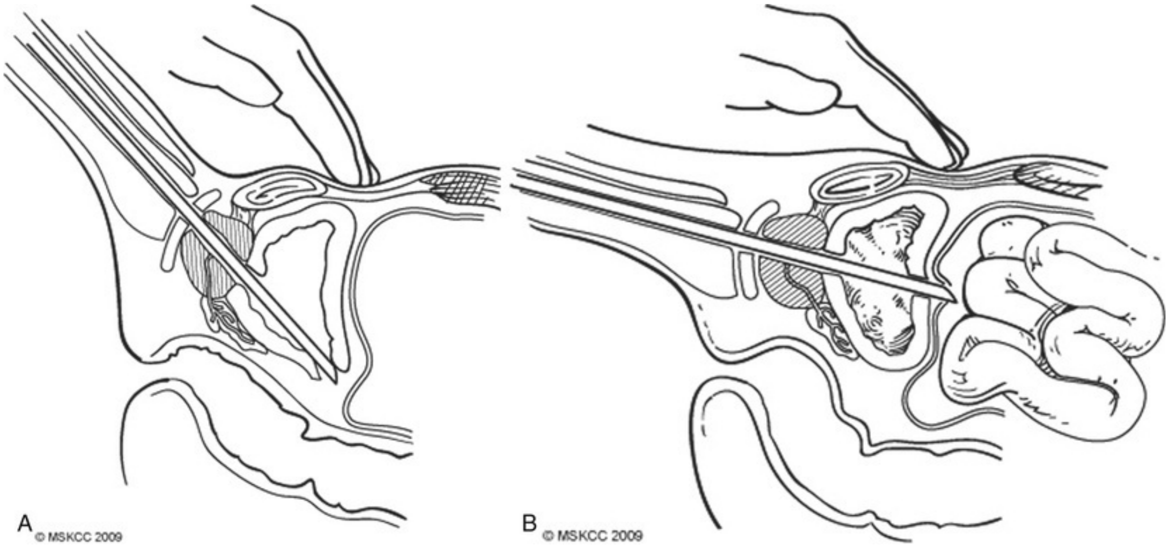

FIG. 138.3 (A) Extraperitoneal bladder rupture during transurethral resection (TUR) of a bladder tumor. (B) Intraperitoneal bladder rupture during TUR of a bladder tumor with subsequent intraperitoneal leakage of irrigant and urine. (A and B, Copyright 2009 Memorial Sloan Kettering Cancer Center.)

Although data would suggest little to no effect on progression rates, adjuvant intravesical chemotherapy has demonstrated efficacy in reducing recurrences (Kurth et al., 1997). A meta-analysis of 18 randomized controlled trials for a pooled cohort of 3103 patients showed that a single dose of intravesical chemotherapy (e.g., mitomycin C, epirubicin) within 24 hours after TUR of non–muscle-invasive bladder tumor resulted in a 13% absolute reduction in tumor recurrence from 50% to 37%, yielding a number needed to treat of 7.2 (Abern et al., 2013). **Further data supporting the use of perioperative chemotherapy are demonstrated by the recently published Southwest Oncology Group (SWOG) trial S0337. Messing et al.** (2018) **conducted a randomized double-blind trial comparing perioperative gemcitabine (2 g in 100 mL of saline) to saline alone (100 mL) immediately after TUR. The treatment was very well tolerated, with no grade 4 or 5 toxicities, and produced an absolute reduction in recurrences of 12% at 4 years (HR 0.66, $P < 0.01$).** Caution should be applied, however, and adjuvant therapy should only be administered in the absence of perforation. In the setting of high-grade non–muscle-invasive disease, bacille Calmette-Guérin therapy remains the most active agent but should not be administered in the immediate postoperative setting. Rather, a waiting period of 2 to 4 weeks should be observed and a lack of gross hematuria confirmed before administration.

Patient Preparation

In advance of surgical therapy for bladder cancer, appropriate preoperative staging and medical evaluation should be performed. **Patients with adequate renal function and an absence of allergy to iodinated contrast can be staged with CT of the chest, abdomen, and pelvis. In instances in which renal function is impaired, MRI can be substituted.** This allows for assessment of distant and regional disease spread and can guide the use of neoadjuvant chemotherapy. Although studies have been conducted examining novel agents for the detection of lymph node metastasis (Birkhäuser et al., 2013) and comparing MRI and CT accuracy (Vargas et al., 2012), CT currently remains the most common modality for staging. A retrospective analysis of 100 patients by Baltaci et al. (2013) demonstrated an accuracy of 72% and 86% for the detection of perivesical invasion and lymph node metastasis, respectively. In a smaller study of 16 patients comparing MRI with CT imaging accuracy in determining final T stage, CT was correct in 63%, overstaged in 31%, and understaged in 6% (Vargas et al., 2012).

After confirmation before surgery of localized disease, patients should undergo routine medical evaluation to maximize health status. Comorbidities such as coronary artery disease, smoking-related lung disease, and peripheral vascular disease will commonly be encountered. After medical optimization, regardless of preferred urinary diversion, enterostomal therapy should be used for stoma marking. Although rare, patients should be made aware of the possibility of an ileal conduit urinary diversion even in the case of a planned continent diversion. **Careful marking of the ostomy site to avoid interference, in a standing and in a seated position, is performed to maximize appliance fit and to minimize stomal irritation.** If stomal therapists are not available, the surgeon should be familiar with marking strategies and should perform these while the patient is awake and wearing typical clothing.

Mechanical bowel preparation was historically used in the hope of mitigated anastomotic leak, abdominal, and wound infections in patients undergoing bowel surgery. However, the results of two large randomized trials in colorectal surgery have brought into question this assumption. **Ren et al.** (2011) **found, in their study of an enhanced recovery pathway following colorectal surgery, that those who did not undergo a bowel preparation, among other modifications, were no more likely to experience a complication (9.4% vs. 9.7%) and had**

similar rates of anastomotic leak. Another large study of 380 patients who underwent colorectal surgery with or without mechanical bowel preparation showed that wound infection rates (prep vs. no prep 6.4% vs. 5.7%), anastomotic leak (prep vs. no prep 3.7% vs. 2.1%), and abdominal abscess (prep vs. no prep 1.1% vs. 1%) were similar (Zmora et al., 2003). Further study in radical cystectomy patients undergoing ileal conduit urinary diversion demonstrated similar findings (Xu et al., 2010). In addition, a study of 40 patients undergoing radical cystectomy with ileal urinary diversion randomized to either 3-day bowel preparation or overnight fasting showed a lower incidence in prolonged ileus (10% vs. 5%) if bowel preparation was not used (Hashad et al., 2012). For this reason **we advise against routine bowel preparation for patients undergoing radical cystectomy with urinary diversion, especially if only ileal segments are to be used.**

To enhance further the return to bowel function, the μ-opioid receptor antagonist alvimopan should be administered 30 to 90 minutes before surgery; it has been studied and it demonstrates a benefit in functional bowel recovery and length of hospitalization. The results of a phase III multicenter trial of alvimopan administered 30 to 90 minutes before bowel resection and twice daily thereafter indicated that those who received this drug exhibited lower rates of postoperative ileus (7.3% vs. 15. 7%) and a time decrease of 6.2 to 5.2 days for a written discharge order to be provided (Ludwig et al., 2008). A phase IV study examining the same drug in radical cystectomy patients demonstrated a 2.63-day reduction in hospital stays, lower rates of total parenteral nutrition for postoperative ileus (10% vs. 25%), and a cost savings of $2340 to $2640 per patient (Kauf et al., 2014).

Although we do not advise on the routine use of oral antibiotic prophylaxis as an adjunct to mechanical bowel preparation, **intravenous antibiotics should be administered within 1 hour of surgical incision**. The choice of antibiotic should be customized to local bacterial susceptibility patterns and should include gram-positive coverage (skin flora) and gram-negative aerobes and anaerobes (distal small bowel and large bowel flora). Generally a broad-spectrum cephalosporin such as cefoxitin will provide adequate coverage. Last, in the absence of significant bleeding, high-risk **patients should undergo both mechanical thromboembolic prophylaxis (pneumatic compression) and pharmacologic prophylaxis before the induction of general or spinal anesthesia.** Extended prophylaxis in the postoperative period has also been shown to decrease thromboembolic events. A prospective study of 703 patients randomized to either 8 days or 28 days of pharmacologic prophylaxis after abdominal or pelvic surgery showed that those treated for 4 weeks had an 82.4% reduction in the incidence of major venous thromboembolism (0.8% vs. 4.6%) without an increase in bleeding complications (Kakkar et al., 2010).

Patient positioning is vital to provide adequate exposure and to minimize the risk of related complications. Male patients should be placed supine with the flexion point of the table at the level of the anterior superior iliac spine (Fig. 138.4A). Flexion to 15 degrees is usually adequate and can be lessened as necessary if there is a history of spinal fusion or lumbar injury. In women, a low lithotomy position with the aid of stirrups or the use of spreader bars provides access to the vagina. In female patients, table flexion is generally not possible. The operative field should be inclusive of the abdomen from the level of the xiphoid to the upper portion of the thighs. The genital organs, including the vagina in women, and the perineum should be prepared as well. A solution containing 10% povidone-iodine is recommended; preparations containing chlorhexidine gluconate should be avoided when used on genital skin.

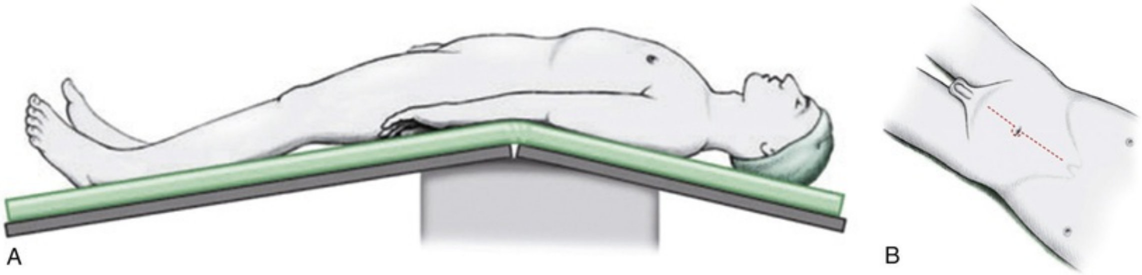

FIG. 138.4 Positioning of the patient in the supine position with the bed flexed to 15 degrees (A). An incision is made in the midline from 2 cm above the umbilicus to just above the level of the pubis (B).

Surgical Technique

A lower midline incision is made sharply extending distally from the level of the symphysis pubis to the umbilicus superiorly. Frequently an infraumbilical incision provides adequate exposure but can be extended cephalad as needed (Fig. 138.4B). Ensuring incision of the abdominal fascia in the midline aids in fascial closure and prevention of inadvertent release of the rectus abdominis from its tendinous insertion at the level of the pubis. Upward retraction of the umbilicus (toward the ceiling) aids in the identification of the linea alba. After the midline is identified, the fascia is divided and the space of Retzius is entered. Blunt dissection is performed to release the bladder from the pelvic sidewall attachments bilaterally. This is carried in a cephalad direction to the level of the vas deferens in men and the round ligament in women. At this point a peritoneotomy is made lateral to either medial umbilical ligament and the urachus is controlled and divided (Fig. 138.5). The peritoneum is incised lateral to the medial umbilical ligaments bilaterally to the level of the internal inguinal rings at which point the vas deferentia in men and the round ligaments in women will be identified and are divided.

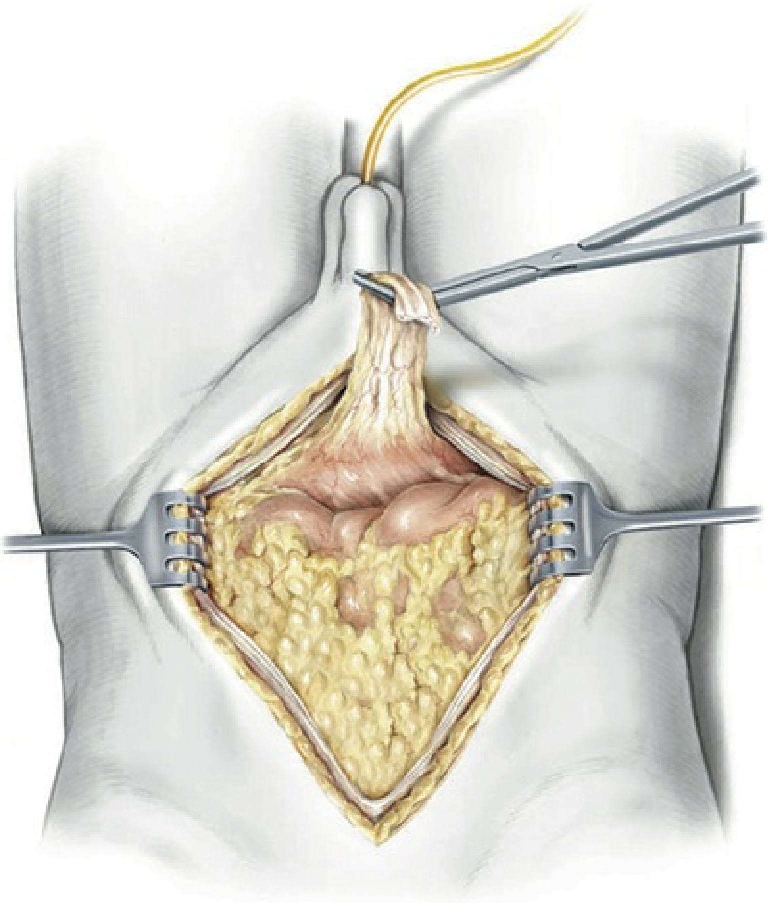

FIG. 138.5 Mobilization and division of the umbilicus.

Attention is then turned to the bowel mobilization to achieve adequate exposure of the great vessels and the ureters. On the right side the white line of Toldt is incised and carried around the cecum where then the posterior peritoneum is incised to allow mobilization of the root of the small bowel mesentery. On the left side the white line of Toldt is likewise incised, and a window is created below the sigmoid colon mesentery to communicate with the right-sided posterior peritoneotomy. This space will later be used to transpose the left ureter to the right lower quadrant for urinary diversion (Fig. 138.6).

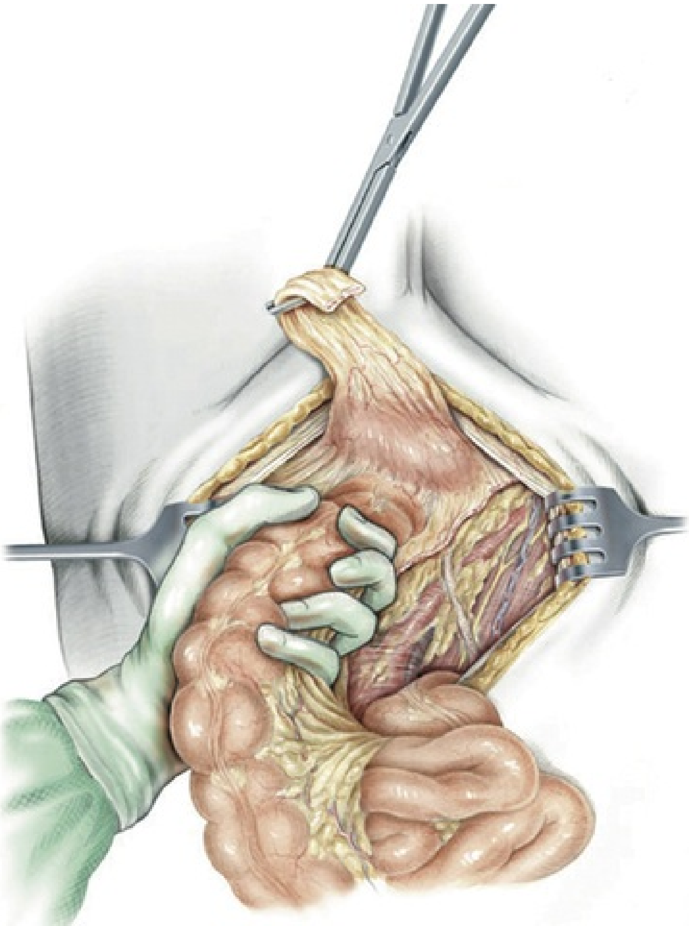

FIG. 138.6 Mobilization of the root of the small bowel mesentery and the left colon.

With the aid of a retractor such as a Bookwalter, exposure is maximized and the bowel retracted cephalad. Communication with the anesthesiologist at this point is vital to ensure that inadvertent compression of the vena cava has not occurred. A moistened laparotomy pad or pads should be placed behind retractor blades to protect the abdominal contents. After adequate exposure is achieved, the bilateral ureters are dissected free from their attachments beginning a few centimeters above where they cross the iliac arteries to the level of the detrusor hiatus. Care should be used to ensure that adequate ureteral adventitia is maintained. The obliterated umbilical artery should be ligated and divided before completing the ureteral dissection; this aids in maximizing ureteral length. The ureter is then controlled with either suture ties or suture ligature and divided.

Although controversial, the distal ureteral margin can be sent for frozen section analysis to evaluate for the presence of urothelial carcinoma. Although **studies have shown a correlation between findings of carcinoma in the**

ureteral margin and subsequent upper tract recurrence (Schumacher et al., 2006), an impact on survival has not been well established (Raj et al., 2006). In addition, the study by Raj et al. (2006) indicated that despite sequential resection to achieve a negative margin in 48 instances of an initial positive ureteral margin, upper tract recurrence was not eliminated. According to surgeon preference, temporary ureteral catheters directed off the surgical field can be used to maintain urinary flow during the remainder of the procedure, or the ureters can be temporarily ligated to avoid spillage of urine into the operative field.

Pelvic Lymphadenectomy

Pelvic lymphadenectomy can be performed at this time or after removal of the bladder specimen according to surgeon preference. **The anatomic boundaries of a standard template dissection consist of the genitofemoral nerves laterally, the internal iliac artery medially, Cooper ligament inferiorly, and the point at which the ureter crosses the common iliac artery superiorly** (Fig. 138.7A). In cases of advanced disease, an extended dissection inclusive of the entire common iliac lymph node packet and the presacral lymph node packet can be obtained (Fig. 138.7B). Although further extension cephalad to include the preaortic packet to the level of the inferior mesenteric artery has been studied in bladder cancer, none have demonstrated any additional staging information beyond a dissection from the common iliac arteries distally (Bochner et al., 2004, Bruins et al., 2014). Care should be taken during lymphadenectomy to avoid injury to the obturator nerve and to ensure control of lymphatics at the caudal and cephalad extremes (Fig. 138.7C) and when complete to confirm that no residual lymphoid tissue remains in the operative field (Fig. 138.7D). Surgical quality as measured by nodal yield has demonstrated a survival benefit in bladder cancer. **Herr et al.** (2004) **found that in patients in whom at least 10 lymph nodes were removed, 5-year survival improved from 44% to 61%.** Later an examination of 1260 patients in the Surveillance, Epidemiology, and End Results data set with lymph node metastatic bladder cancer showed that overall survival improved from a median of 13 months if 1 to 5 nodes were removed to 23 months if 10 or more were removed (Wright et al., 2008).

Completion of the pelvic lymphadenectomy aids in the exposure and identification of the vascular pedicles to the bladder (Fig. 138.8). Control of the main branches to the bladder, including the superior, middle, and inferior vesical arteries, can be achieved with the aid of a vascular stapler (see Fig. 138.8B), surgical clips (see Fig. 138.8A), or vascular sealing instruments.

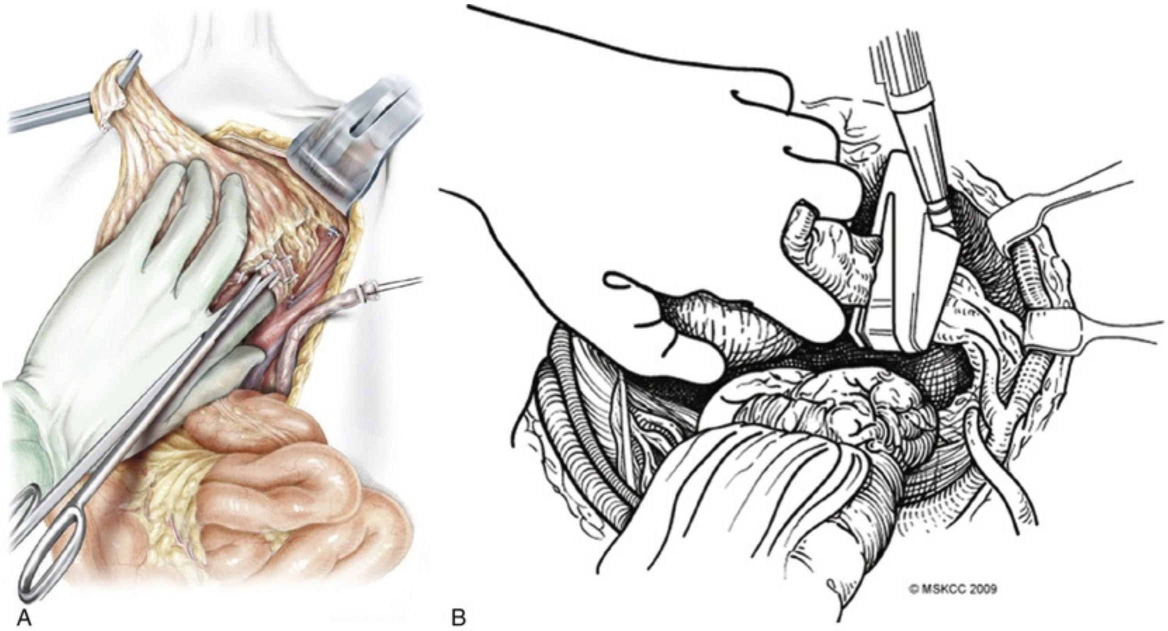

FIG. 138.8 (A) Application of clips to the lateral vascular pedicle of the bladder. (B) Application of an endovascular stapler to the lateral vascular pedicle of the bladder. (B, Copyright 2009 Memorial Sloan Kettering Cancer Center.)

Radical Cystectomy: Male

After the anterior vascular pedicle blood supply is completely ligated, attention is turned to the posterior dissection. The rectal cul-de-sac is identified and the peritoneum is incised where it overlies the seminal vesicles (Fig. 138.9A and B). If there is a large tumor at the base of the bladder, care must be observed to ensure an adequate margin of resection at this point. The rectum is dissected free with either blunt dissection or sharp dissection in the midline and is carried to the level of the prostate, at which point Denonvilliers fascia is encountered and incised. In cases of advanced disease, previous pelvic radiation, or reactive fibrosis from previous resection or intravesical chemotherapy, difficulty in developing this plane may be encountered. In such instances blunt dissection should not be performed, because this may cause inadvertent injury to the rectum. Instead, under direct visualization, sharp dissection should be performed with care taken to maintain rectal integrity. If a rectal injury is encountered, primary repair with or without flap coverage and/or bowel diversion should be performed (Kozminski et al., 1989). After release of the rectum in the midline, dissection is carried laterally and the posterior vesical pedicles are identified (Fig. 138.10A). Similar to the anterior pedicles, they can be controlled with surgical clips, ties, vascular staplers, or sealing instruments (Fig. 138.10B). **Care should be taken, however, if sealing instruments are used: the heat they generate can transmit and may injure the rectum if in close proximity. With a gloved finger, the surgeon should shield the rectum from the tips of such instruments while in use.**

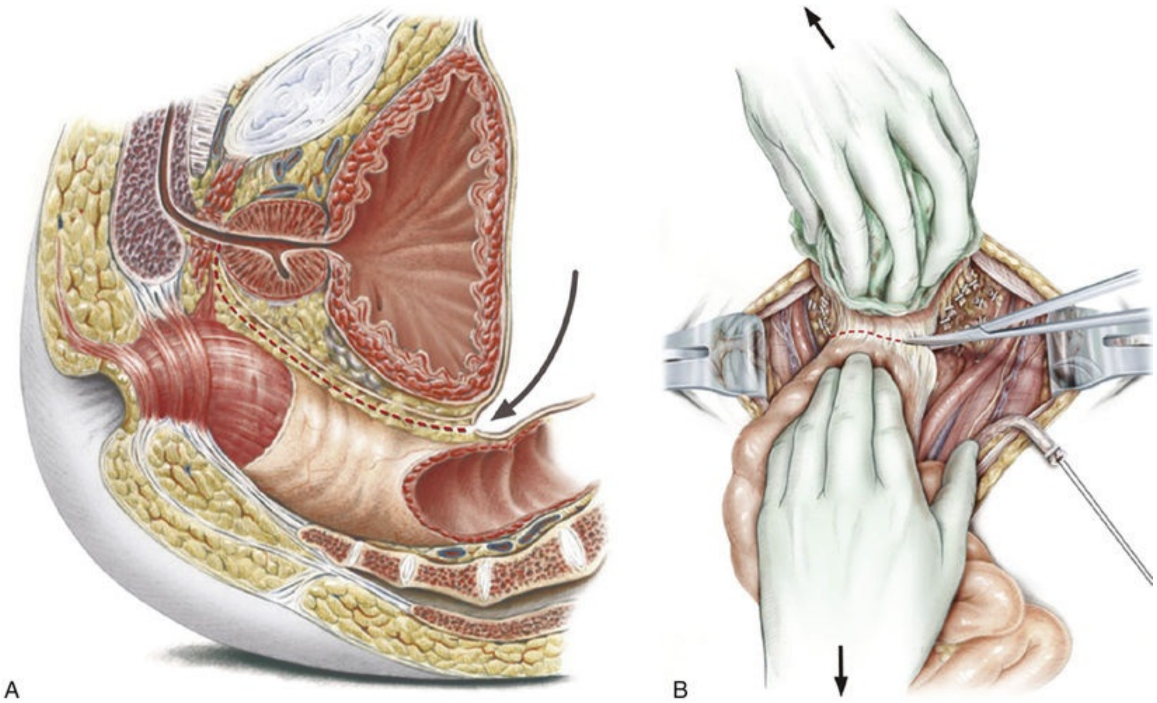

FIG. 138.9 (A) The posterior plane beyond the cul-de-sac, which separates the bladder and prostate from the rectum. (B) Division of the peritoneum overlying the rectum in the cul-de-sac.

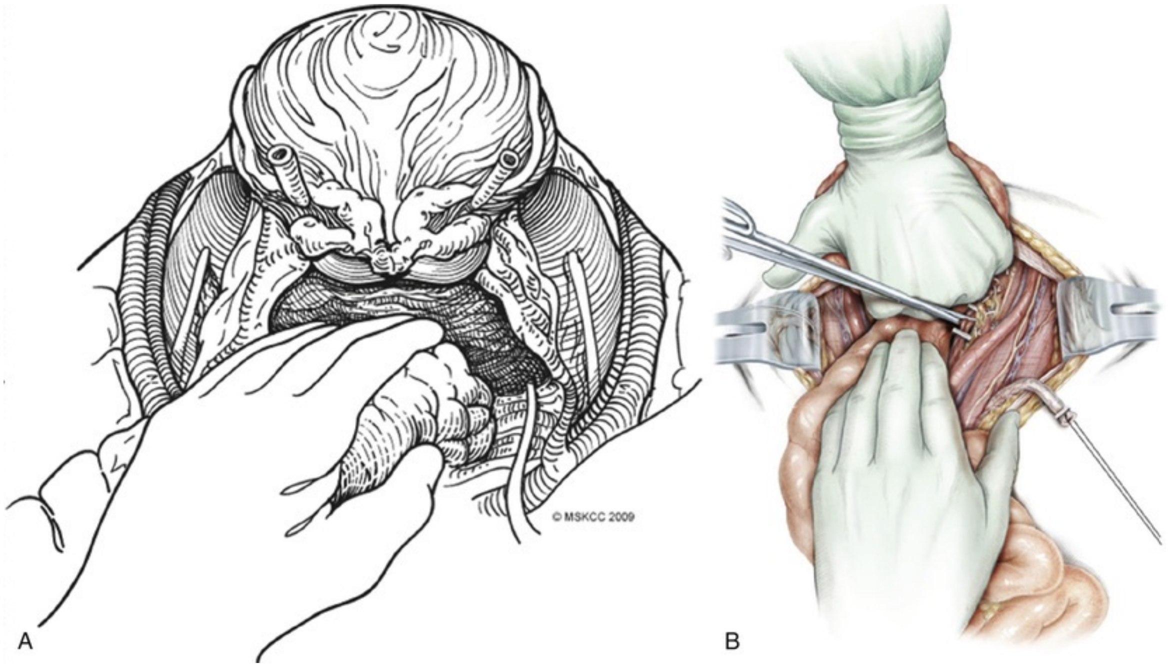

FIG. 138.10 (A) Exposure of the posterior vascular pedicle of the bladder for ligation. (B) Ligation and division of the posterior pedicle. (A, Copyright

2009 Memorial Sloan Kettering Cancer Center.)

After completion of the posterior dissection, the urethra should be palpable, and at this point attention can be turned to the anterior dissection in a fashion similar to a radical prostatectomy. The endopelvic fascia overlying the levator muscles is incised sharply, allowing for identification of the confluence between the urethra and the dorsal venous complex. Ligation and division of the dorsal venous complex (Fig. 138.11) allows for visualization of the anterior urethra, which is then incised.

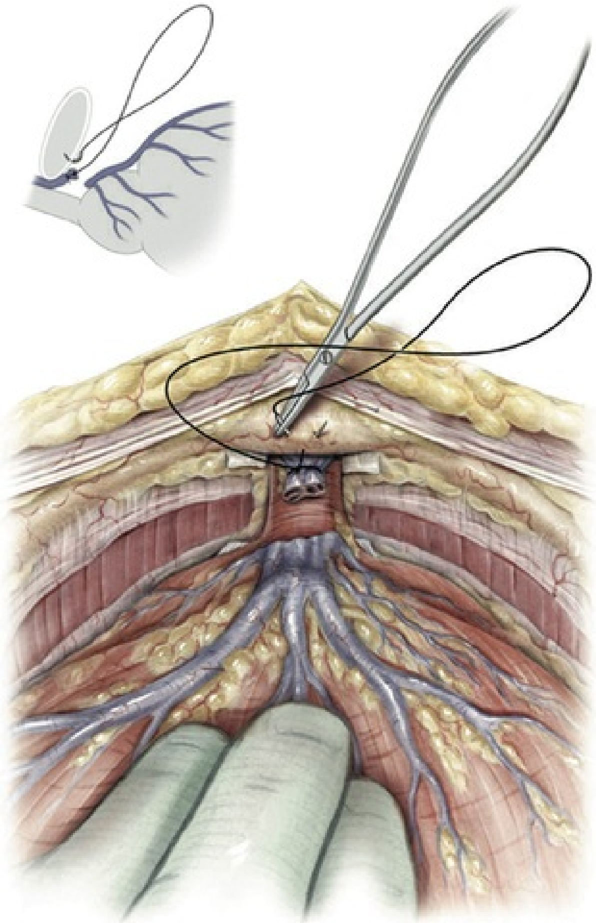

FIG. 138.11 Division of the dorsal venous complex.

If continent ileal neobladder urinary diversion is planned, adequate urethral length must be maintained and a frozen section analysis of the urethral margin performed. In a study of 436 patients who underwent eight cutaneous or orthotopic diversions, urethral recurrence occurred in 7.9% of patients at 5 years and at a median of 1.6 years after radical cystectomy

(Freeman et al., 1996). In addition, the study demonstrated that patients with an orthotopic diversion were at lower risk of urethral recurrence (4% vs. 10%), although the reason is unclear. In another study of 118 male patients after radical cystectomy, no patients with a negative intraoperative urethral frozen section had a urethral recurrence at 10 years of follow-up (Lebret et al., 1998). A large study examining the usefulness of preoperative prostatic urethral biopsy in predicting final urethral margin status demonstrated poor correlation (68%), but very high negative predictive value (100%) if the intraoperative frozen section was negative (Kassouf et al., 2008). We therefore recommend that in the presence of a positive urethral margin, orthotopic neobladder should not be performed and the patient should be made aware of this possibility during preoperative counseling.

The role of preservation of the neurovascular bundles, unlike in radical prostatectomy, remains controversial in radical cystectomy. A technique analogous to radical prostatectomy (Fig. 138.12A and B) can be applied; however, the functional outcomes remain significantly worse. In a report of erectile dysfunction in sexually active men treated with radical cystectomy, Zippe et al. (2004) found in their series of 49 men that only 6 of 16 (38%) who underwent nerve-sparing surgery were naturally potent after surgery, and only 7 of 49 (14%) were potent when including all patients (nerve-sparing and non–nerve-sparing). These results do not differ significantly from reports of men who underwent non–nerve-sparing cystectomy as reported by Asgari et al. (2013). In that study of 81 sexually active men, they found that at 1 year only 9.8% (ileal conduit) to 35% (neobladder) regained function sufficient for vaginal penetration and maintenance of erection until the completion of intercourse (Asgari et al., 2013). Among men who underwent nerve sparing, age, similar to the radical prostatectomy series, is a strong predictor of functional recovery with a drop from 62% potency for men aged 40 to 49 years to 20% for those 70 to 79 years (Schoenberg et al., 1996). In addition, in their report of 101 patients only 5 (5%) suffered a local recurrence; however, caution should be noted as one was a patient with pT2 disease. The risks and benefits of nerve sparing should be judged according to preoperative sexual function and disease burden. **Non-nerve sparing** (Fig. 138.13) **is the preferred choice in advanced disease and in patients with preexisting erectile dysfunction.**

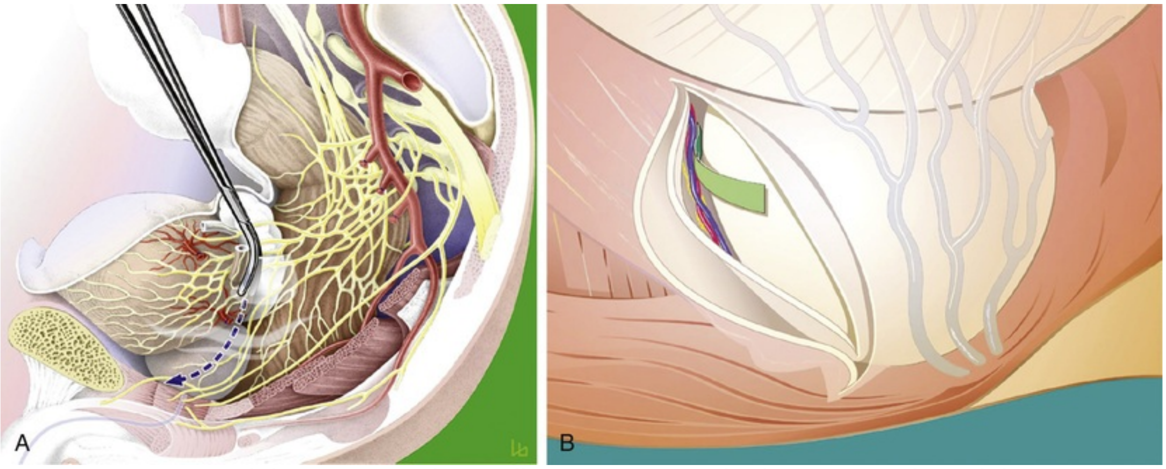

FIG. 138.12 (A) Nerve-sparing radical cystectomy in the male patient. (B) Separation of the plane between the prostatic capsule and the neurovascular bundle.

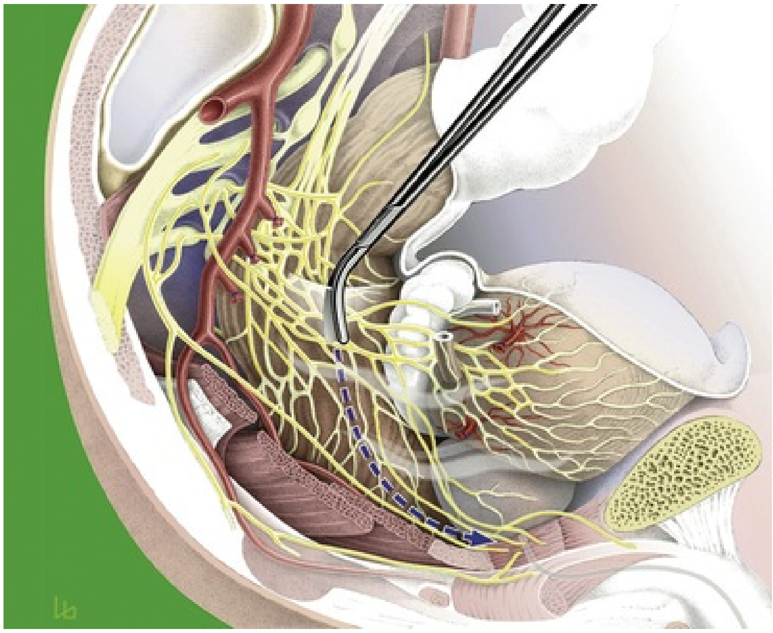

FIG. 138.13 Non–nerve-sparing radical cystectomy in the male.

Additional efforts have been used to improve sexual functional outcomes, including subtotal resection of the prostate. Described techniques include leaving the prostate in its entirety or sparing the prostatic capsule and/or the seminal vesicles. These approaches have largely been studied in the context of orthotopic neobladder urinary diversion. In the setting of nonurothelial cancers, Spitz et al. (1999) showed that erectile and ejaculatory function could be maintained in 3 of

4 patients. In another report, Colombo et al. (2004) showed excellent erectile function outcomes in all of the 27 patients and no instances of local recurrence; however, follow-up was limited to only 32 months. There is, however, concern because of the high rate of occult prostate cancers in radical cystectomy specimens. This has been shown to be as high as 41% in larger series (Revelo et al., 2004). Despite this, in highly selected patients, excellent local control can be maintained. In a study of 100 patients without evidence of prostate cancer preoperatively and negative frozen section at surgery, only 5 (5%) developed local recurrence, although distant metastasis did develop in 31 patients (Vallancien et al., 2002). To achieve such outcomes, however, proper patient selection is paramount. Preoperative evaluation should include DRE, prostate-specific antigen (PSA) testing, transurethral prostatic resection, and intraoperative frozen section analysis. In the setting of PSA or DRE abnormality prostate biopsy should be done in advance of surgery.

Radical Cystectomy: Female

Radical cystectomy in women historically included total anterior pelvic exenteration inclusive of the bladder, urethra, anterior vagina, uterus, and cervix. This allows for adequate resection and is vital in the presence of a positive EUA or if there is concern for anterior vaginal wall invasion (cT4a). Compared with men, women are seen initially with more advanced disease (Kluth et al., 2013; Mitra et al., 2014). In addition, in the study by Kluth et al. (2013) of more than 8000 patients, in multivariable analysis female gender was an independent risk factor for death from disease (hazard ratio [HR] = 1.17 [range 1.05 to 1.31], *P* = 0.005) (Kluth et al., 2013). For this reason, anterior pelvic exenteration remains the gold standard of therapy. As discussed later, however, in patients with low-stage disease (cT1 and cT2) in whom orthotopic neobladder is considered, vaginal and urethral sparing is necessary.

As described earlier, the initial steps for bowel mobilization, anterior bladder mobilization, and ureteral dissection are the same in men and in women with the exception of the gonadal vessels. In female patients the ovarian vessels should be identified during the bowel mobilization and ligated with a 2-0 silk suture distally, and a 2-0 silk suture ligature and a tie proximally, and then divided. Anterior pelvic exenteration begins with identification of the posterior cervical fornix (Fig. 138.14A), and the vaginal cuff is incised at this position (Fig. 138.14B). After gaining entry to the vaginal canal, the surgeon easily can control the lateral and posterior vascular pedicles to the bladder. According to surgeon preference, vascular staplers, sealing devices, or clips are applied, and the specimen can be dissected free inclusive of the uterus, cervix, anterior vaginal cuff, and bladder. The urethral meatus is then incised, either antegrade from the pelvis or externally from the vaginal introitus, and the specimen is removed (Fig. 138.15A and B). Care should be taken to ensure that sufficient vaginal mucosa is maintained above the urethral meatus to allow for closure of the vaginal defect in subsequent steps. Because of the vascular nature of the female pelvis and the sinusoidal nature of the vascular pedicles as they pass over the lateral vaginal wall, care is needed to ensure hemostasis. To complete the vaginal closure with a 2-0 polyglactin 910 suture, often the posterior vaginal wall must be released from the rectum (Fig. 138.15C). The posterior vaginal flap is then closed to the corresponding mucosae of the introitus in a clamshell fashion to maintain vaginal girth at the cost of some vaginal length. **Bothersome drainage of**

peritoneal fluid will result if the vaginal closure is not watertight, and an interrupted closure is preferred. A vaginal packing is then placed with the dual purpose of distending the vagina and providing tamponade to any residual vaginal wall hemorrhage (particularly useful if vaginal sparing is performed; discussed later) and aids in the identification of unrecognized defects in the closure. This packing should be removed 2 days postoperatively.

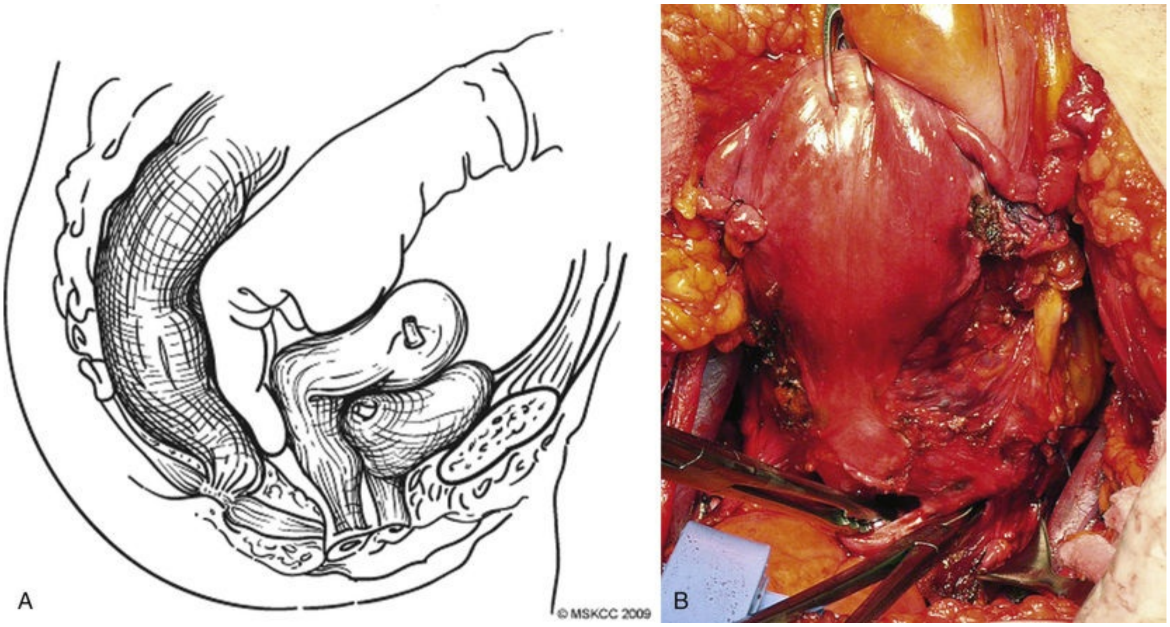

FIG. 138.14 (A) Identification of the vaginal cuff posterior to the cervix. (B) Incision of the posterior vaginal cuff. (A, Copyright 2009 Memorial Sloan Kettering Cancer Center.)

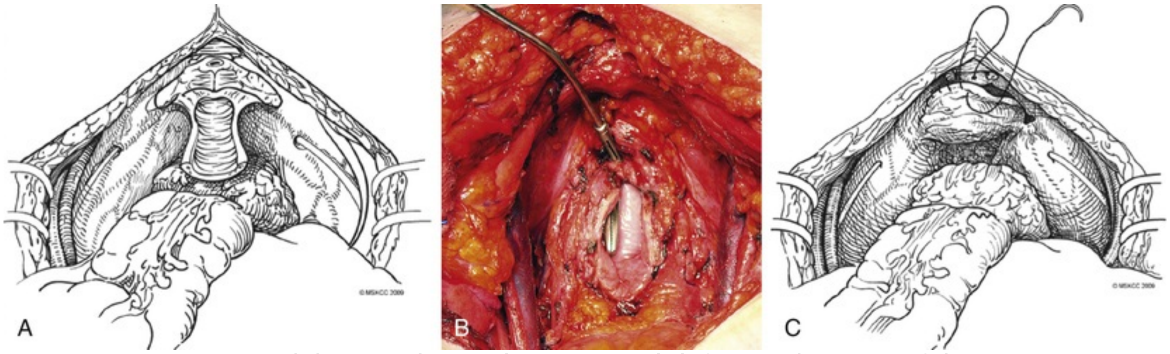

FIG. 138.15 (A) Posterior vaginal wall and defect at the level of the introitus after en bloc removal of the bladder in an anterior pelvic exenteration in the female patient. (B) Intraoperative photograph of the introital defect. (C) Coverage of the introital defect with a flap made from

the posterior vaginal wall.

In the absence of bladder neck involvement and the presence of low-stage disease (≤cT2), orthotopic neobladder can be considered. This necessitates urethral sparing with adequate length proximal to the striated sphincter and anterior vaginal wall sparing to provide support to the neobladder. As described previously, the lateral vascular pedicles are intimate with the lateral wall of the vagina, and to control these vessels properly they must be separated from the vagina before ligation. This can be achieved either after removal of the cervix and uterus at the level of the cervical fornix (Fig. 138.16A) or while they are still in place. A vaginal packing during this step can aid in defining the plane of separation between the bladder and the anterior vaginal wall in the midline. Alternatively an end-to-end anastomosis (EEA) sizer can be introduced into the vagina. This can serve as a vaginal manipulator as well as providing vaginal distention. After development the dissection plane between the posterior bladder and the anterior vagina is extended laterally, separating the lateral vascular pedicles from the lateral vaginal wall. To ensure that an adequate bladder margin is maintained, the vessels should not be divided until the midpoint of the lateral vaginal wall, in the anterior posterior plane, has been reached. This dissection is carried to the level of the bladder neck, which can easily be identified by use of the Foley catheter balloon as a guide. Maintaining the integrity of the striated sphincter, the specimen is removed at this level (Fig. 138.16B), and a frozen section of the urethral margin is sent and managed in the same fashion as in male neobladder candidates. Again, if the urethral margin analysis demonstrated malignancy, orthotopic diversion is contraindicated. The vaginal apex is closed with 2-0 polyglactin 910 sutures and urethral anastomotic sutures placed (see Fig. 138.16BC).

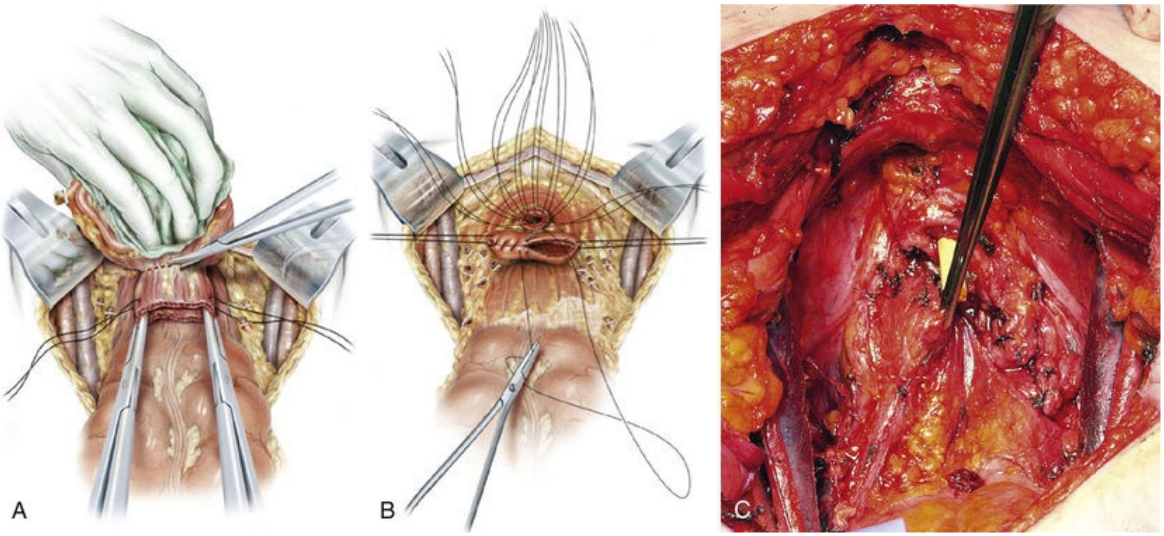

FIG. 138.16 (A) Circumferential division of the vaginal cuff from the attachments to the cervix. (B) Closure of the vaginal cuff and placement of the urethral anastomotic sutures. (C) Intraoperative photograph of the completed repair.

Partial Cystectomy

Consideration for bladder-sparing surgery in the setting of muscle-invasive urothelial carcinoma requires proper patient selection. **For those with solitary lesions of small size and who lack concurrent carcinoma in situ (CIS), results from partial cystectomy are similar to those of radical cystectomy.** In an analysis of 37 such patients treated at the MD Anderson Cancer Center, 9 (24%) developed either a muscle-invasive and/or metastatic recurrence; however, the 5-year overall and the disease-specific survival rates were 67% and 87%, respectively (Kassouf et al., 2006). In a population-based matched cohort study examining partial versus radical cystectomy when matched for surgical quality (number of lymph nodes removed) and clinicopathological features, partial cystectomy was equivalent in terms of overall and cancer-specific survival (Capitanio et al., 2009). Patients initially treated with partial cystectomy can be salvaged with radical cystectomy; however, survival is significantly worse for locally advanced disease at the time of salvage. In patients with organ-confined disease, 5-year survival is 60%, whereas it is only 7% for extravesical disease (Bruins et al., 2012).

In the select patients who are candidates for partial cystectomy, preoperative preparation includes counseling regarding the possibility of radical cystectomy and the discussion of urinary diversion, because it is possible that an adequate margin will not be possible or extravesical disease will be encountered. Partial surgical removal includes pelvic lymphadenectomy, as described earlier, as well as anterior bladder mobilization. Cystotomy is performed in an area away from the tumor. The tumor is then excised, including the underlying bladder wall and perivesical fat with a mucosal margin of 1 to 2 cm and confirmation of resection adequacy with frozen section analysis. If necessary, the ureteral orifice or intramural ureter can be excised and a reimplantation performed. After excision of the tumor the cystotomy is closed with 2-0 polyglactin 910 suture in 2 or 3 layers, and instillation of fluid via a Foley catheter is performed to ensure a watertight closure. Copious warm water irrigation of the surgical field is performed to minimize the possibility of pelvic seeding. A closed suction drain should be placed and the cystotomy closure interrogated with a cystogram on postoperative day 7 before removal of the Foley catheter.

Although rare, primary adenocarcinoma arising from the urachus requires additional resection. These tumors are most commonly confined to the dome of the bladder, although they may grow by direct extension to involve other areas. A circumferential incision around the umbilicus is made and extended toward the pubis. Complete excision includes the umbilicus, the urachus, and the dome of the bladder with a visual margin free from tumor (Fig. 138.17). Again this is confirmed with frozen section analysis, and additional resection may be necessary. Bladder augmentation with the use of an intestinal segment can be performed if bladder capacity is significantly reduced.

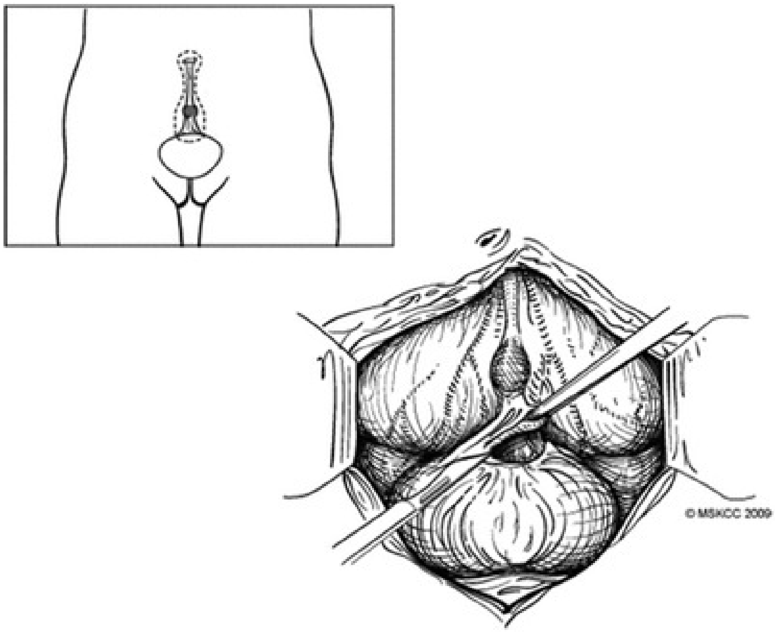

FIG. 138.17 Resection of an adenocarcinoma of the urachus. (Copyright 2009 Memorial Sloan Kettering Cancer Center.)

Robotic Radical Cystectomy

Background

Bladder cancer patients pose a broad array of challenges to clinicians, which are further heightened when the burden of their disease requires radical cystectomy. Whether it be the frequent coexisting medical conditions such as pulmonary and cardiac disease, or the commonly encountered frailty and diminished performance status, bladder cancer patients are rarely straightforward to manage clinically. In addition, given the advanced age at which many patients are seen, they frequently have had prior complicating abdominal surgeries and as a result a thoughtful surgeon must approach surgical decision making carefully.

In light of these myriad challenges, efforts have been implemented to improve patient outcomes. Among these are refinements in the surgical technique, better understanding of proper patient selection, and optimization of perioperative care. As discussed earlier in this chapter, enhanced recovery pathways should be employed whenever possible. A result of these strategies has been a generally shortening of hospitalization and earlier return of bowel function after surgery. What has remained stubbornly high, however, are complications and blood transfusion rates.

Naturally as clinicians search for ever more elusive improvements in patient outcomes, we draw upon experiences in other disease sites. Building on a large collection of data demonstrating advantages for minimally invasive surgery in the areas of complications and blood loss the application of these techniques to bladder cancer care seemed inevitable. The large-scale adoption of laparoscopic and robotic techniques in other urologic disease sites provided a stepping stone. A progression was witnessed in which surgical techniques moved from laparoscopic simple cystectomy, to laparoscopic radical cystectomy with extracorporeal diversion, followed by robotic radical cystectomy and lymphadenectomy (Pruthi et al., 2008) and later intracorporeal urinary diversion (Desai et al., 2014). Despite these advances the universal application of robotic surgery to radical cystectomy has been met with headwinds.

Not unlike the early criticisms of robotic radical prostatectomy, initially the resistance concerned oncologic equipoise, in which a lack of tactile feedback and technical limitations were thought to favor open surgery. **Unlike prostate cancer, for which effective salvage therapy exists, oncologic outcomes in**

bladder cancer are uniquely vulnerable to surgical misadventure. In cases of urinary spillage, inadequacy of the lymphadenectomy, or soft tissue margin positivity, disease recurrence is nearly universally accompanied by death from disease.

In an effort to assuage the concerns of the urologic community, investigators focused their initial studies on pathological outcomes (Davis et al., 2011; Nix et al., 2010). Using a non-inferiority design Nix et al. (2010) conducted a prospective randomized trial in 41 patients comparing nodal yields between open and robotic radical cystectomy and lymphadenectomy. In both arms patients underwent an open urinary diversion. They found no difference in nodal yields (mean 19 vs. 18, robot vs. open, $P = 0.515$). Secondary end points included a demonstration of improved blood loss (mean 273 vs. 564 mL, robot vs. open, $P = 0.0003$), time to first bowel movement (3.2 vs. 4.3 days, robot vs. open, $P = 0.0033$), and decreased morphine equivalents while an inpatient (93.6 vs. 151.6 mg, robot vs. open, $P = 0.0110$) for robotic surgery. However, there was a significant increase in operative times for robotic surgery as well (4.2 vs. 3.5 h, $P \leq 0.0001$).

In the study conducted by Davis et al. (2011) at the MD Anderson Cancer Center, 11 patients underwent a complete robotic extended lymphadenectomy followed by an open, second look, dissection. The purpose of this study was to determine the adequacy of a robotic lymphadenectomy. The median lymph node yield for the robotic technique was 43 (range 19–63) and only a median of 4 (range 0–8) additional lymph nodes resected during the open, second look dissection. In no cases did the additional nodes removed by a second look open dissection result in a pathological stage change (Davis et al., 2011). The results of these studies bolstered the preliminary oncologic efficacy of the robotic technique, leading to larger studies aimed at determining the long-term cancer outcomes and preliminary evidence for a possible benefit to perioperative recovery.

Two notable randomized trials provide some further evidence to support the oncologic efficacy of robotic radical cystectomy but leave questions into the impact on surgical outcomes and complications. Reported as a correspondence in the *New England Journal of Medicine* and in more detail in *European Urology,* Bochner et al. (2014) published results of a single-intuition randomized trial comparing robotic and open radical cystectomy and lymphadenectomy with a primary end point of 90-day complications. The study design employed an open urinary diversion in both arms, which some argue may have had a direct impact on their primary end point. At the mandated interim analysis the study closed as a result of futility after demonstrating a similar grade 2 to 5 (by modified Calvien) complication rate (62% robotic 66% open) (Bochner et al., 2014). The by-randomization and the intention-to-treat analysis demonstrated similar pathological outcomes: no difference in complications, but an improvement in blood loss at the expense of a more costly operation and longer operative times.

The RAZOR trial has provided the highest level of evidence supporting the oncologic efficacy of robotic cystectomy and lymphadenectomy. Published in *The Lancet*, Parekh et al. (2018) showed non-inferiority for robotic cystectomy and lymphadenectomy with a primary end point of 2-year progression-free survival (72.3% vs 71.6%, robot vs. open, $P = 0.001$). Similar to the study by Bochner et al. open urinary diversion was employed in both arms. However, we do not suspect an open urinary diversion should have had any effect on the primary end point of progression-free survival. Consistent with previous study, the RAZOR trial demonstrated lower blood loss, transfusions rates, and shorter hospitalizations for patients treated in the robotic arm.

The role and rationale for minimally invasive bladder cancer surgery nevertheless remain an unsettled question. Although utilization trends for robotic radical cystectomy have not mirrored those seen during the transition to robotic radical prostatectomy (Pak et al., 2017), the demonstration of oncologic equipoise is only likely to further fuel interest in the procedure. Coupled with a stubbornly high rate of complications after radical cystectomy, surgeons naturally will seek tools and techniques to improve patient outcomes. However, **the primary focus must remain on oncologic outcomes, and as a result we do not feel there is compelling evidence to suggest superiority for either robotic or open radical cystectomy.**

Patient Selection

The indications for minimally invasive radical cystectomy are no different from conventional open surgery and follow the same preoperative staging paradigm as described earlier. There are, however, special considerations resulting from the patient position in steep Trendelenburg and the need for pneumoperitoneum. Chief among these are anesthetic concerns as a result of possible increased pulmonary pressures, ventilation mismatch, increased intraocular pressure, and decreased cardiac output (Hsu et al., 2013). These concerns should be discussed and addressed before the day of surgery, and we strongly advise open and thoughtful exchange of information between all team members to ensure patient safety remains paramount.

Specific surgical concerns are more challenging to quantify and characterize. For instance, prospective trials of robotic radical cystectomy have excluded those patients with prior abdominal surgical history. Although rigid criteria such as this may ensure more straightforward access to the peritoneal cavity and easier dissection, we do not feel prior abdominal or pelvic surgery is a strict contraindication. Individual experience will dictate each surgeon's ability to assess and allay such challenges. **However, we would caution against, especially early in the learning curve, the use of robotic technique in patients who have had prior urologic surgeries such as partial cystectomy or ureteral reimplantation. These cases are particularly challenging and may increase the risk of a positive surgical margin in inexperienced hands.**

Another frequently encountered patient selection concern relates to obesity. Not only do larger patients pose positioning challenges but also the increased abdominal weight on the diaphragm while in Trendelenburg position increases the ventilation challenges faced by the anesthesia team. Again, we advise a team approach to the decision making in these cases and open communication during the procedure. **Whenever in doubt, using an open approach or conversion to an open approach after initial robotic access to ensure patient safety is advised.**

Please note that for the purposes of this chapter the robotic technique described will be specific to the Da Vinci Surgical System by Intuitive Surgical. As technologies evolve, the principles herein should provide an framework for adopting the technique to new devices and instrumentation.

Patient Positioning

As with robotic radical prostatectomy, the details of patient positioning for robotic radical cystectomy vary by surgeon preference and case-by-case concerns. A one-size-fits-all approach rarely suffices in surgical planning, and this is even more evident in the radical cystectomy population. Specific concerns relating to prior radiation therapy, increased possibility of rectal or bowel related complications, preservation of sexual and endocrine function, limitations to the range of motion in an extremity and prior prosthetic reservoirs in the operative field represent a short, incomplete list of the challenges that may be faced. As a result of these and other possible challenges, patient positioning and docking strategies should be tailored on a case-by-case basis.

The advances afforded by the Da Vinci Xi system, and specifically the rotating overhead boom, can prove very useful in the bladder cancer population. The Xi system provides easier docking from the side of an operative bed and in some cases eliminates the need for lithotomy positioning. We routinely employ a right-sided docking approach in male and female cases whenever the Xi system is used. In the setting of a male radical cystectomy we generally keep the patient in supine position as well. However, in female cases in which vaginal access is required, or in male patients where rectal complications are more likely (e.g., prior prostatectomy or prostate radiation) maintaining dorsal lithotomy is advised. Even in these circumstances we advise docking the robot from the patient's right because it allows ease of access to the area between the patient's legs should an assistant need to relocate to that area.

When using a robotic system without a rotatable boom (e.g., Da Vinci S, Si, or X system), we still advise that the robot be docked between the legs with the legs in lithotomy position because arm conflicts are bothersome with a side-docking strategy when using these devices.

Another common challenge encountered when performing robotic pelvic surgery is patient migration, or sliding, toward the head. Patient migration may be more pronounced during robotic bladder surgeries, which are among the longest robotic pelvic surgeries performed by urologists. We have devised a useful technique to prevent patient migration through the application of 3M Reston foam. Before the patient is transferred to the operative bed, 3M Reston foam, which has an adhesive side, is adhered to the operative bed such that the area of the operative bed directly under the torso of the patient is covered in a layer of foam. The adhesive prevents the foam from moving relative to the operative bed, and the foam interfaces with the patient skin, passively preventing pressure injury and mitigating patient sliding.

The arms are then tucked at the sides and a chest strap with foam padding is placed approximately at the level of the mid-chest to secure the patient to the bed. If the patient has been placed in supine position, additional straps are placed with foam padding over the legs (Fig. 138.18).

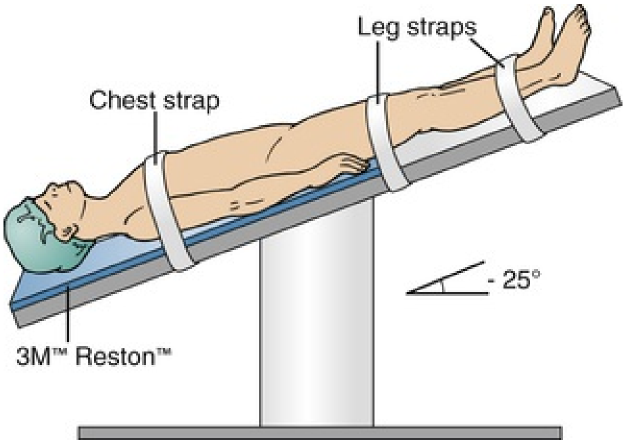

FIG. 138.18 Illustration of patient positioning when docking from the right side is applicable. Note the use of 3M Reston foam under the thorax to prevent patient migration while in Trendelenburg position.

Port and Assistant Placement

Optimal port placement has a profound impact on multiple aspect of the case, most notably the lymphadenectomy and urinary diversion (not discussed in this chapter). Extended lymph node dissections, which are commonplace in bladder cancer surgery, require an analogous transposition of the ports in a cephalad direction as compared with robotic prostate cancer surgery. In addition, if a robotic urinary diversion is to be performed, the right-sided ports benefit from a more cephalad placement. We have found the port placement strategy demonstrated in Fig. 138.19 to be ideal in cases in which an intracorporeal or extracorporeal urinary diversion is planned.

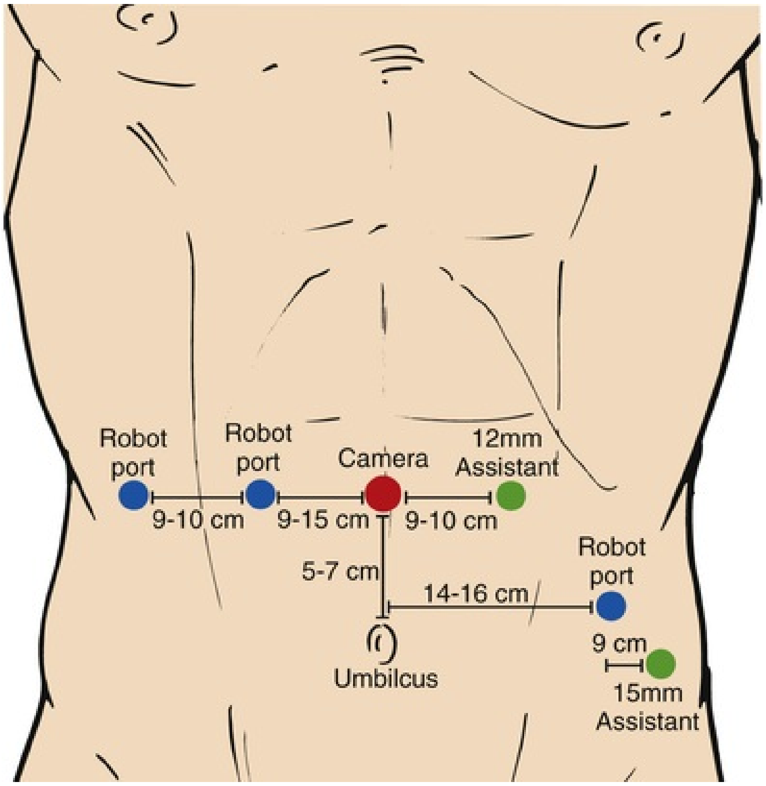

FIG. 138.19 Optimized port placement strategy for robotic radical cystectomy (male and female). Camera placement 5 to 7 cm above the umbilicus with two right-sided robotic ports placed in a level line with the camera spaced 9 to 10 cm apart. A left-sided robotic port placed 14 to 16 cm lateral to the umbilicus and just above the level of the umbilicus. A left-sided 12-mm assistant port is placed 9 to 10 cm lateral to and in level with the camera port. Last, a 15-mm assistant port is placed 9 cm lateral to the left robotic port and just below the level of the umbilicus.

A detailed discussion on the initial access to the peritoneum is not presented here, but our routine has been to insufflate to 15 mm Hg via a Veress needle after a meniscal drop test. We then place a camera port and inspect the abdominal cavity while the patient is still flat to aid in the identification of an inadvertent injury before placing the patient in Trendelenburg and proceeding with the additional port placements.

Key aspects of our port placement strategy included a camera placement, 3 to 4 fingerbreadths (5–7 cm) above the umbilicus and right-sided robotic ports at this level. The right-sided ports are placed in a straight line 9 to 10 cm apart. The high placement of these ports aids in the dissection of the terminal ileum and cecum if a robotic urinary diversion is planned. The left-sided robotic port can be placed closer to the pelvis at a level in line with the umbilicus. The left-sided robotic port is placed farther from the camera (approximately 15 cm) than the right-sided port to provide space for a 12-mm assistant port (can be substituted with a 5-mm port), which is placed between the left robotic port and the camera. Last, a 15-mm assistant port is placed just cephalad to the anterior superior iliac spine. We have found that a 15-mm port at this location provides an excellent angle for stapling the bowel if a robotic urinary diversion is planned and the increased port size allows for large lymph node packets to be removed en bloc. In addition, the 15-mm port provides access for a large Endo Cath bag used to retrieve the bladder specimen. It has also been our routine to place port closure sutures at the site of the 12-mm and 15-mm assistant ports at the time of port placement as opposed to the end of the procedure. We do so with an O polyglactin 910 suture passed with the aid of a Carter-Thomason CloseSure System. The choice of port closure technique is largely surgeon preference and alternative approaches can be employed.

In the technique described here we place a single surgical assistant on the left of the patient and use a four-arm robot configuration with two robotic arms on the right. After port placement and placing the patient in approximately 25-degree Trendelenburg position, the robot is docked. This is done either between the legs or on the right of the patient as described earlier. Insufflation pressure can be reduced according to surgeon preference.

Instrumentation

The choice and location of robotic instruments varies by surgeon preference. A thorough understanding of the grasping strength, intended use, and limitations of the available instruments helps guide an individual surgeon's choice. Table 138.1 provides our current recommendations, but be advised that the robotic systems are rapidly evolving and the instrumentation is likely to change. Familiarizing yourself with the available tools and their specific characteristics allows you to adjust the instruments to your specific needs and preferences. The following principles will help guide these decisions.

TABLE 138.1

Robotic System Recommendations

ARM NUMBER (FROM PATIENT LEFT TO RIGHT)	INSTRUMENT	NOTES
1	Maryland	

	bipolar forceps	
2	Camera	0 degree
3	HotShears (monopolar curved scissors)	
4	Cadiere Forceps	Limited grasping of the bowel with care and under direct vision. (Second Cadiere Forceps in arm 1 during urinary diversion construction)
1 and 3	Large needle driver	Optional Large SutureCut needle driver (particularly useful during continent urinary diversion)

First, we have found the monopolar curved scissors (right medial robotic port) and the Maryland bipolar forceps (left medial robotic port) to be optimal for the majority of our dissection needs. In addition, the Cadier forceps (right lateral robotic port) provides sufficient strength for retraction while limiting the risk of crush injuries when compared with the commonly used ProGrasp (Mucksavage et al., 2011). This may allow for limited and careful manipulation of the bowel. For suturing we favor the use of the large needle drivers, although when performing an intracorporeal neobladder reconstruction the use of a large SutureCut needle driver can improve efficiency. Only in very rare cases have we found the need to use the 30-degree up or down camera lens, and nearly all cases are done with the use of 0-degree lens. This includes lymphadenectomies extending into the low retroperitoneum (e.g., paracaval, para-aortic, and pre-aortic).

Sigmoid Release and Posterior Dissection

There is high variability in the degree of sigmoid attachments to the left pelvic peritoneum as well as within the sigmoid peritoneum. Generally this dissection is best performed by first releasing the sigmoid peritoneal attachments that generate the S-shaped curve to the sigmoid intestine. In doing so the weight of the sigmoid colon then helps auto-retract the large bowel out of the pelvis. As a result, the fourth robotic arm or bedside assistant is available to provide other forms of assistance because retracting the sigmoid colon in cephalad direction is not needed. To accomplish this maneuver we have found that contrary to instinct, whereby most surgeons would retract the sigmoid colon to the right, grasping the sigmoid distal to the S curve and retracting in a cephalad direction provide the best visualization of the sigmoid peritoneal adhesions.

Once the sigmoid curvature is released by incising these peritoneal attachments, the remaining pelvic sidewall and left white line of Toldt dissection is straightforward (Fig. 138.20A–C). Once the white line of Toldt is released as far proximally as possible, the interface of the sigmoid mesentery and the left ureter can be visualized. Incision of the peritoneum just medial to the left ureter prevents violation of the sigmoid mesentery and should maintain the dissection in an avascular plane (Fig. 138.20D–F). Care should be employed to ensure the dissection over the presacral lymph node packet is maintained in this avascular plane and the sigmoid mesentery is not violated. Even small amounts of bleeding in this area quickly obscures visualization. We have found that, if bleeding is encountered during this dissection, it generally indicates dissection into the sigmoid mesentery and the dissection plane should be adjusted. Whenever possible the dissection should be continued until the right common iliac artery is identified (Fig. 138.20F). This will provide ample visualization for the presacral lymphadenectomy and transposition of the left ureter, which is described later. **A helpful visual tool throughout the sigmoid release is that mesenteric fat is a darker yellow than the retroperitoneal or lymphatic fat. Looking for this visual demarcation can significantly aid dissection in the proper tissue planes.**

Lateral Space of Retzius and Anterior Vascular Pedicle Dissection

After the sigmoid mesenteric release and the posterior dissection (male patients) attention is brought to the lateral dissection. In a female patient in whom a concurrent oophorectomy is planned, the ovarian vessels should be controlled at this point. They will be visualized similarly to the gonadal vessels seen in Fig. 138.20. We advise controlling the ovarian vessels with two clips on the proximal end and one clip on the distal end before transection. Our practice is to use large Weck clips for this purpose.

The approach to the lateral space of Retzius shares commonality with robotic radical prostatectomy. Care should be employed to ensure an adequate amount of perivesical fat is maintained on the bladder. Fig. 138.22A–D demonstrates the stepwise progression of the lateral dissection. The obliterated umbilical artery (medial umbilical ligament) is grasped and retracted medially. Retraction in this manner exposes the peritoneal interface of the bladder and anterior abdominal wall (Fig. 138.22B). Incision of the peritoneum in this plane is carried to the internal inguinal ring, where the vas deferens is controlled in men and the round ligament is controlled in women. Our practice is to control these structures with bipolar cautery, although clips can be used. Care should then be applied to the dissection in the space of Retzius to avoid violation of the perivesical fat medially and the pelvic lymph nodes laterally. The dissection is extended to the endopelvic fascia (Fig. 138.22C) distally and the hypogastric artery posteriorly (Fig. 138.22D). In the case of a male cystectomy the endopelvic fascia is incised in a manner similar to a radical prostatectomy. Variation on the approach to the endopelvic dissection, in accordance to nerve sparing (e.g., high release), can be employed.

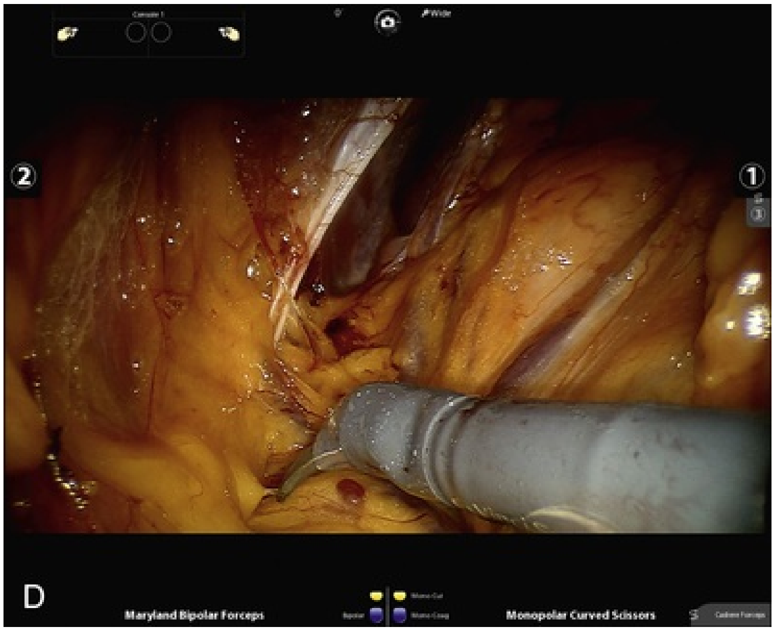

FIG. 138.22 (A) Lateral space of Retzius dissection (left side shown). (B) Tension on the left medial umbilical ligament clearly demarcates the interface between the bladder and the anterior abdominal wall. (C) The dissection is advanced distally to the endopelvic fascia and (D) posteriorly to the hypogastric artery.

Once the space of Retzius is exposed, the anterior vascular pedical of the bladder can be controlled. Although bipolar cautery can be used, we favor Weck clips, which we find provide superior vascular control and avoid heat transmission should nerve sparing be performed. Upward and medial retraction of the obliterated umbilical artery aids in developing the space between the ureter (medially) and the origin of the obliterated umbilical. After retraction is applied, the avascular plane medial to the anterior vascular pedicle comes into view (Fig. 138.23A). The pedicle vessels are then controlled sequentially toward the endopelvic fascia with clips (Fig. 138.23B). Frequently a broad venous branch from the distal hypogastric vein is present just proximal to the endopelvic fascia (Fig. 138.23C) and, once divided, serves as a reliable landmark that a complete anterior vascular pedicle dissection (Fig. 138.23D) has been performed.

FIG. 138.23 Anterior bladder pedicle dissection. (A) Isolation of the initial portion of the obliterated umbilical artery. (B) Transection of the clipped initial portion of the obliterated umbilical artery. (C) Isolation and (D) control of the distal venous tributaries just proximal to the endopelvic fascia. (E) Left ureter and (F) elevation to aid in dissection.

Mobilization of the ureter is aided by retracting upward on the bladder close to the detrusor hiatus (Fig. 138.23E). This technique will elevate the ureter and should provide access to the tissue plane adhering the ureter to the pelvic vasculature. The ureter can easily be retracted bluntly with the nontraumatic portions of the robotic instruments and bipolar cautery used to control perforating vessels. Care should be taken to never directly grasp the ureter, even with robotic instruments of lower grasping strength.

The mobilization of the ureter continues proximally above the common iliac artery (Fig. 138.23F). Ample periureteral adventitia should always be maintained to mitigate ischemic strictures.

We do not find that vessel loops or other retraction aids are necessary because careful retraction of the ureter is possible by using the smooth, distal surfaces of the robotic instruments in a blunt manner. **In addition, after ureteral mobilization we do not find that it is necessary to control and transect the ureter at the detrusor hiatus at this point in the procedure. Instead we advocate for completion of the lymphadenectomy first while maintaining antegrade flow of urine into the bladder.** Later in the procedure an analogous dissection is performed on the right sided.

Extended Pelvic Lymphadenectomy

Although the pelvic lymphadenectomy can be performed after completion of the radical cystectomy, we feel this unnecessarily necessitates ureteral occlusion for potentially prolonged periods of time. In addition to the potential adverse effects on renal function postoperatively, occlusion of the ureters disadvantages the anesthesia team by withholding a valuable clinical indication of the patients resuscitative status. We have also found no reliable advantage to occlusion-induced dilation the ureters in aiding the ureteral anastomoses. Last, we have found no hindrance to visualization or access to the lymphadenectomy field with the ureters in continuity.

The anatomic landmarks for a complete extended pelvic lymphadenectomy are described earlier and do not differ when performed robotically as compared with open. However, visual clues are interpreted differently because of the differences in the visual angle of the camera as opposed to the overhead view while the surgery is performed via a laparotomy. We provide some technical pointers to ensure a meticulous dissection is performed.

External Iliac Lymphadenectomy

The external iliac lymph nodes frequently extend behind the spermatic cord. Before retraction of the spermatic cord, as seen in Fig. 138.24A, it is unclear where the external iliac lymph node packet ends laterally. Lateral retraction on the spermatic cord (Fig. 138.24B) delineates the lateral border of the lymph node packet and provides an assurance of a complete dissection in this area. Without this lateral retraction maneuver on the spermatic cord, a dissection across this tissue could lead to inadvertent transection of lymph nodes. Release of the lymph node packet laterally is then extended over the top of the artery (Fig. 138.24C,D) and inclusive of the tissue between the external iliac artery and vein. The tissue is then separated from the obturator lymph node packet, in a natural cleavage plan that does not lead to lymph node transection, and carried distally to the inferior epigastric vessels (Fig. 138.24D). Care should be taken to avoid inadvertent injury to the genitofemoral nerve, which has a variable branch point. Many times the femoral branch (parallel to the external iliac artery) and inguinal branches (traveling into the internal inguinal ring) will be recognized and should be released from the lymph node packet as needed. In cases of advanced disease if there is dense adherence of the nerve to the lymph node packet, an en bloc resection may be required. Whenever possible the lymph node packet should be kept as a single specimen (Fig. 138.24E) and placed immediately into a retrieval bag (Fig. 138.24F). The use of a 15-mm assistant port provides ample capacity to remove large lymph node packets, eliminating the need for dissection of the packet into smaller pieces. This aids efficiency but most importantly avoids transection of lymph nodes.

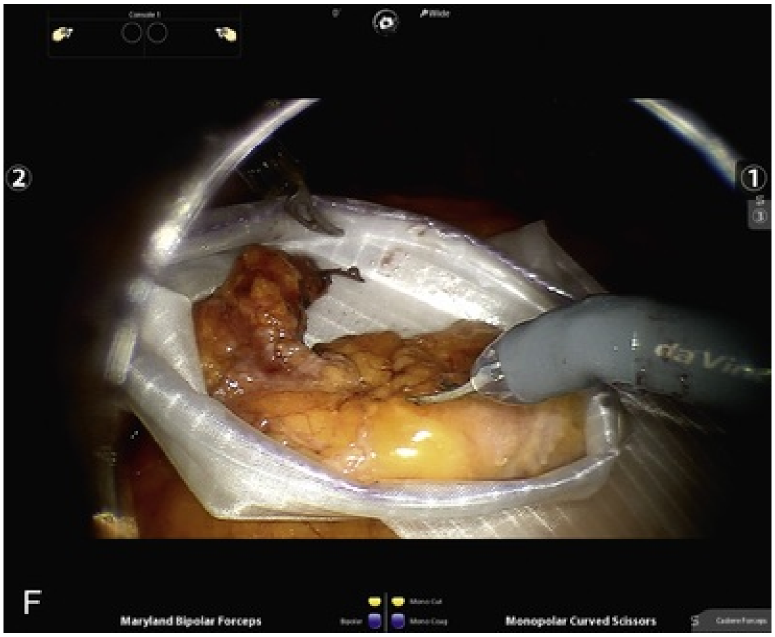

FIG. 138.24 The left external iliac lymphadenectomy is demonstrated. (A) The lymph node packet can be seen extending behind the spermatic cord (B), which is retracted laterally to ensure completeness of the lymph node dissection. (C) The skeletonized external iliac arteries are shown and the (D) interface between the external iliac and obturator lymph node packets is visualized. (E) An en bloc lymph node packet is then (F) placed into a retrieval bag.

Obturator Lymphadenectomy

The obturator lymph node packet can now easily be viewed (Fig. 138.25A). With the aid of gentle retraction by the assistant suction tip (Fig. 138.25B) on the external iliac artery, the lymph node packet can be released from the vein wall. Carefully the packet is released from the lateral pelvic sidewall attachments, and bipolar cautery is used to control lateral perforators. A common misconception is that the obturator nerve serves as the posterior landmark for this dissection; however, to complete this dissection the release of tissue lateral and posterior (toward the patient's back) should extend until the wall of the hypogastric vein is appreciated (Fig. 138.25C). As the packet is released off the hypogastric vein wall, a complete dissection is ensured. Once completed, the obturator fossa should be bare of nodal tissue (Fig. 138.25D). Although this approach may capture a portion of the hypogastric lymph nodes with the obturator specimen, we have found that an attempt to dissect the packet at the level of the obturator nerve laterally frequently leads to nodal transection and as such is ill advised.

FIG. 138.25 (A) Initial elevation of the obturator lymph nodes from the external iliac vein and (B) pelvic sidewall. (C) The obturator nerve is demonstrated and the dissection carried posterior and lateral to the nerve. (D) The dissection is complete and the obturator fossa cleared of nodal tissue.

Hypogastric Lymphadenectomy

Attention is then paid to the internal iliac lymph node packet. Deep to the obturator nerve and extending to the lateral pelvic sidewall toward the endopelvic fascia the nodal tissue can be seen (Fig. 138.26A). In a manner analogous to the obturator dissection the nodal tissue is released from the pelvic sidewall (Fig. 138.26B) and released. The hypogastric nodal packet extends posteriorly around the mesorectal fascia, and care must be employed to ensure a complete packet is removed (Fig. 138.26C). Gentle upward retraction aids in the release of this deep portion of the packet, and once completed, the pelvic portion of the lymphadenectomy is complete (Fig. 138.26D).

FIG. 138.26 (A) The hypogastric (internal iliac) lymph node packet is released from the (B) pelvic sidewall distal and posterior to the obturator nerve. (C) The nodal tissue extends posteriorly just lateral to the mesorectal fascia and once released (D) the dissection is complete.

Common Iliac Lymphadenectomy

Following a similar dissection technique to that described earlier, the left common iliac lymph node packet is identified (Fig. 138.27A) and removed. The initial release begins from the lateral border of the common iliac artery (Fig. 138.27B) and progresses posteriorly until the left common iliac vein wall can be seen. The tissue is then released in a lateral direction and excised (Fig. 138.27C). Once complete the left ureter, which had been medially retracted, is seen over the lymphadenectomy bed (Fig. 138.27D). The right-sided common iliac dissection is performed in a similar fashion (not shown).

FIG. 138.27 (A) The left common iliac lymph nodes are shown and the initial dissection (B) begins with elevation of the nodal packet off the lateral border of the common iliac artery and continues until the left common iliac vein is identified. (C) The nodal packet is elevated and after completion (D) the ureter can be seen over the cleared fossa.

Presacral Lymphadenectomy

The initial dissection posterior to the sigmoid mesentery performed during the early mobilization is now fully appreciated. Having already released the sigmoid mesentery to the right common iliac artery from the left side, the peritoneum overlying the right common iliac artery is thinned (Fig. 138.28A). Once incised, it is easy to gain continuity with the left-sided dissection and gain full visualization of the presacral nodal basin (Fig. 138.28B). Careful dissection with the use of bipolar cautery to control perforating branches allows for complete excision of the presacral lymph node packet (Fig. 138.28C).

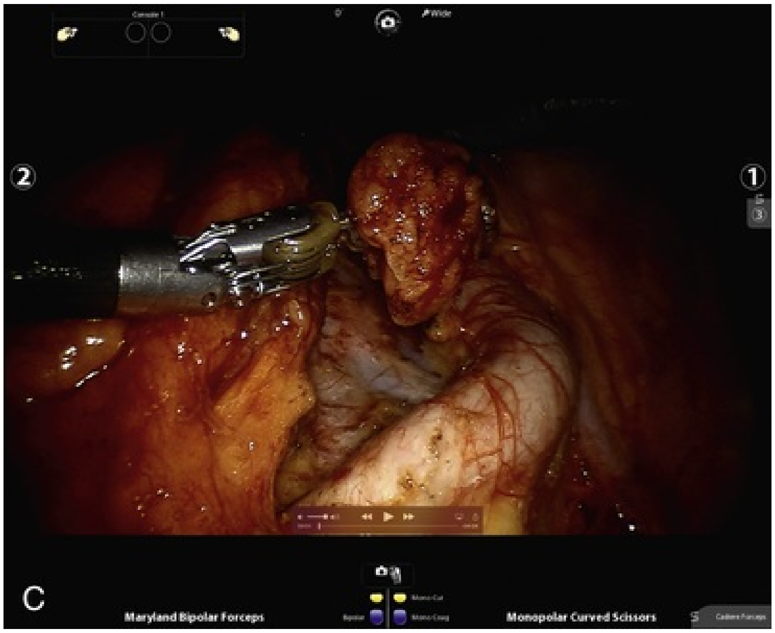

FIG. 138.28 (A) The presacral lymph node packet is identified directly below the sigmoid mesentery (as seen from right to left). (B) With visualization of the aortic bifurcation the nodal packet is carefully elevated (C) off the left common iliac vein and the presacral space.

Oncologic considerations may dictate an alteration to the lymphadenectomy described earlier. For example, the dissection can be extended into the retroperitoneum, or portions of this dissection may be omitted. For example, in non–muscle-invasive disease in which nerve sparing is planned, a presacral dissection may be avoided to mitigate the risk of interrupting the hypogastric plexus proximal to the neurovascular bundles. As discussed earlier in this chapter, the decision regarding the extent of lymphadenectomy is made based on specific cancer characteristics and functional goals.

Ureteral Control and Posterior Pedicle Dissection

After completion of the pelvic lymphadenectomy the ureters are controlled at the detrusor hiatus. If there is oncologic involvement of the trigone, or suspected disease in the intramural ureters, the placement of clips and transection of the ureters can be moved proximally. The placement of clips on the distal right ureter is shown in Figs. 138.29A and B. Adequate space is provided between clips to allow for a ureteral margin to be sent (Fig. 138.29C). Once this has been completed on both sides, the left ureter is transposed to the right lower quadrant under the sigmoid mesentery (Fig. 138.29D). We have not found sutures attached to the ureteral clips, as tethers, to be necessary or helpful. If an adequate release of the sigmoid mesentery has been performed transposition of the left ureter should not be difficult.

FIG. 138.29 (A) The right ureter is shown dissected to the detrusor hiatus (B) where it is controlled with clips. (C) After transection a frozen section is sent. (D) The left ureter is transposed under the sigmoid mesentery to the right low quadrant.

After the ureters have been dissected free the posterior vascular pedicle should be controlled before release of the urachus and anterior space of Retzius. This aids in visualization of the posterior tissues. In the case of a male cystoprostatectomy upward retraction of the bladder with the rightmost robotic arm will aid in the dissection (Fig. 138.30A). In this demonstration the vessel sealer is used but can be easily substituted for clips if nerve sparing is desired.

As the dissection is carried toward the genitourinary diaphragm (Fig. 138.30B) the prostatic pedicle is encountered (Fig. 138.30C) and ultimately ends at the prostatic apex (Fig. 138.30D).

FIG. 138.30 (A) The posterior vascular pedicle of the bladder is visualized by retracting the bladder upward and toward the opposite shoulder. (B) The pedicle is controlled with a vessel sealing device (clips can be substituted) and (C) the prostatic pedicle is identified. (D) The dissection is carried distally to the prostatic apex.

Male Apical Dissection

Male radical cystoprostatectomy can then be completed in a manner similar to radical prostatectomy. We advise releasing the urachal attachments with bipolar cautery and performing an apical prostatic dissection after controlling the dorsal venous complex with a suture ligature. We prefer a 2-O V-loc suture placed in a figure-of-eight fashion and then suspended anteriorly by passing the suture through the synchondrosis of the pubic symphysis (Fig. 138.31A). Once the urethra is isolated (Fig. 138.31B), the Foley catheter should be removed and the urethra controlled proximally and distally and transected. If an orthotopic diversion is planned, a proximal clip should be placed but not a distal urethral clip (Fig. 138.31C). As in an open procedure, a distal urethral margin is sent. A useful technique to aid collection of a urethral margin is to do so by partially transecting the urethra close to the proximal clip (see Fig. 138.31C) then adjusting the urethral transection a few millimeters distally. This then allows a distal margin to be excised (Fig. 138.31D) more easily than attempting to do so after the specimen is fully released.

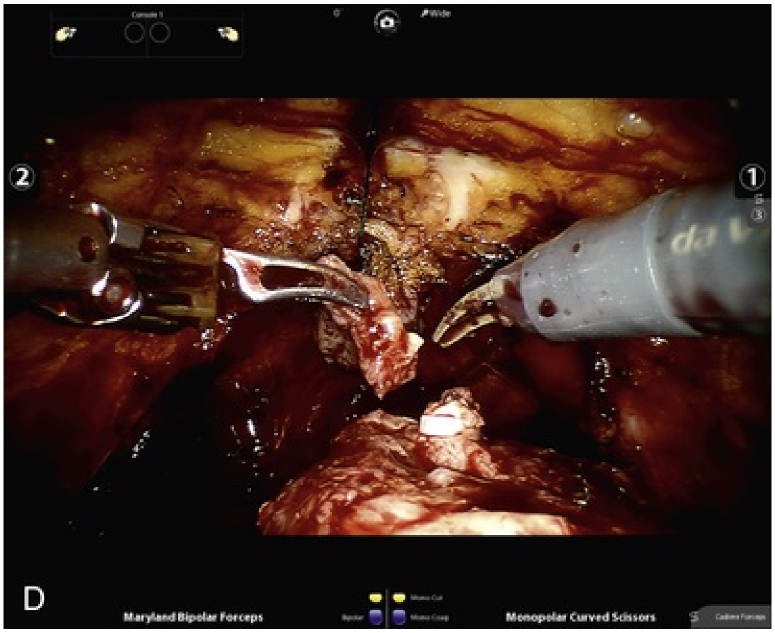

FIG. 138.31 (A) The male dorsal venous complex is controlled and after transection the (B) urethra identified. (C) A proximal clip is placed after the Foley catheter is removed to isolate the bladder contents from the operative field. (D) A urethral margin is isolated during the urethral transection.

Female Radical Cystectomy

As with open surgery, a female radical cystectomy presents unique challenges surgically. A traditional en bloc resection with the uterus and ovaries can be accomplished in the same manner robotically as with an open technique. To aid in the identification of the posterior cervical fornix, or the apex of the vagina if a hysterectomy had been previously performed in the patient, we have found that EEA sizers work very well. These circular sizers can be placed vaginally by the beside assistant and manipulated easily to provide ample countertraction. This provides retraction in the desired direction but also distends the vaginal wall, which can aid in the development of the vaginal sparing plane, described later.

If an en bloc resection of the gynecologic organs and anterior vagina are to be performed after the posterior cervical fornix is opened, the vessel sealer can be used to control the anteriolateral wall of the vagina toward the introitus. Once the dissection reaches the urethral meatus, a useful technique to ensure a complete resection of the urethra and an adequate surrounding vaginal cuff is to detach the Foley catheter from the drainage bag and have the assistant place a clip across the catheter to occlude any urine outflow. The catheter is then passed intracorporally and can be used to retract and visualize the urethral meatus with the robotic instruments.

Vaginal-sparing radical cystectomy can also be performed and is demonstrated in Fig. 138.32. In this example the patient has her uterus in situ. Upward retraction is placed on the bladder with the fourth robotic arm (Fig. 138.32A), and the assistant places an EEA into the vagina, creating countertraction toward the patient's head. The peritoneum is then incised, exposing the anterior vaginal wall (Fig. 138.32B) and the dissection carried toward the introitus in the midline. Commonly this tissue plane is avascular or nearly avascular. The dissection is carried laterally, defining the posterior vascular pedicle in a manner analogous to what is seen during a male case (Fig. 138.32C). The pedicles can be controlled with clips or a vessel sealer (in this example) to the level of the urethral meatus (Fig. 138.32D). At this point if a neobladder is planned, the apical dissection can be completed after release of the urachus and anterior attachments. If urethral sparing is not planned, the vagina can be opened just posterior to the bladder neck and the catheter manipulation described earlier (Figs. 138.32E,F). This technique again ensures a complete urethral and meatal resection.

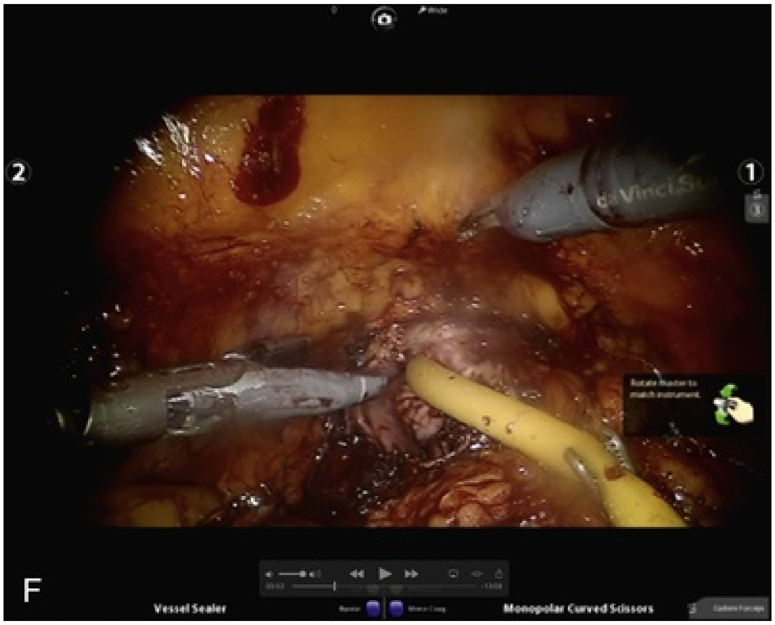

FIG. 138.32 (A) Identification of the vesico-uterine pouch is aided by placement of an end-to-end anastomosis into the vagina by the bedside assistant. (B) The bladder is retracted toward the anterior abdominal wall and the peritoneum incised allowing identification of the anterior vagina. (C) The dissection is then carried forward (distally) to the bladder neck in the midline and the posterior vascular pedicles are isolated laterally. (D) After controlling the posterior vascular pedicles the anterior vagina can be seen in this vaginal sparing example. (E) The vaginal cuff inclusive of the urethral meatus is aided by manipulation of the Foley catheter to ensure (F) a complete excision is performed.

The vaginal defect can be closed according to surgeon preference in a clamshell fashion. We favor a running closure with 2-O V-loc suture; however, alternative approaches include interrupted or figure-of-eight 2-O polyglactin 910 suture. Of paramount concern is achieving excellent apposition of mucosa to mucosa and a watertight closure because peritoneal fistula and prolonged vaginal leakage will result if the closure is not meticulous. We prefer a Premarin or similarly coated vaginal packing be placed and removed on postoperative day 2 to aid in postoperative hemostasis. In the case of an en bloc anterior vaginectomy, frequently the vaginal defect is sufficiently large enough to accommodate specimen extraction. Following oncologic principles, the specimen is immediately placed in a retrieval bag. Extraction is then performed by carefully removing the bag via the vaginal defect while monitoring the tension on the retrieval bag. If at any point the bag fails to progress out or there is concern the vagina or bag may tear, vaginal extraction should be abandoned. Extraction of the cystectomy specimen can then be performed by slightly elongating the midline abdominal port site at the end of the procedure.

Postoperative Care

Radical cystectomy is a complex procedure involving not only the genitourinary but also the gastrointestinal tract because of urinary diversion. In addition to this complexity, patients are frequently elderly and have significant comorbidities. Although major complications are infrequent (13%), any complication remains common (64%) with the most frequent being gastrointestinal (29%) or infectious (25%) (Shabsigh et al., 2009). Postoperative efforts are necessarily directed at minimizing the possibility of complications and maximizing the return of normal physiology. Immediately after surgery, laboratory results including cell count, electrolytes, and renal function are assessed and fluid dynamics are monitored. Frequently patients require initial observation in intensive care or stepdown units. Routine nasogastric suction is not needed; however, it is considered in compromised mentation or known issues with airway protection. As discussed earlier, thromboembolic prophylaxis should be continued in the postoperative setting in the absence of hemorrhage. In addition to pharmacologic measures, early ambulation should be used and pulmonary exercise (incentive spirometry) with deep breathing and coughing should be encouraged.

Delayed return of bowel function frequently prolongs hospitalization after radical cystectomy. Medications such as alvimopan can be used, which has been shown to improve return of bowel function and to shorten hospital stays. Additional postoperative steps to enhance recovery include neostigmine (with telemetry monitoring) to encourage further the return of bowel function, promotility suppositories, stress ulcer prophylaxis, antiemetics, early enteral feeding in the absence of nausea and/or emesis, and avoidance of narcotic pain medication (ketorolac and acetaminophen unless contraindicated) (Djaladat and Daneshmand, 2013).

Key Points

- Bladder cancer is a common cancer associated with high cost and frequent fatality.
- Radical cystectomy offers excellent survival for organ-confined disease.
- TUR is diagnostic and therapeutic, especially for low-grade tumors.

- Perioperative intravesical chemotherapy decreases recurrence rates by 13%.
- A standard template pelvic lymphadenectomy includes the genitofemoral nerves laterally, the internal iliac artery medially, Cooper ligament inferiorly, and the point at which the ureter crosses the common iliac artery superiorly.
- Ureteral margin frozen section aids in predicting upper tract recurrence, but sequential resection to a negative margin may have no impact.
- Nerve-sparing radical cystectomy aids in the preservation of sexual function and is performed in a manner analogous to radical prostatectomy.
- Subtotal prostatic resection can further enhance return of sexual function but should only be offered in select patients in whom the risk of occult prostate cancer is low.
- Vaginal sparing is appropriate in the absence of locally advanced tumors and allows for orthotopic urinary diversion.
- Partial cystectomy can be considered in rare, solitary urothelial tumors without concomitant CIS.
- Urachal adenocarcinomas are treated with en bloc resection of the umbilicus and dome of the bladder.
- Robotic radical cystectomy provides similar oncologic outcomes when compared with open surgery.
- Enhanced recovery protocols can aid in the recovery of normal physiology after radical cystectomy and can shorten hospital stays.

Acknowledgments

The authors acknowledge Drs. John Stein, Kent Berglund, and Harry W. Herr, whose work on the previous version of this chapter was invaluable in the preparation of the current text.

Use of Intestinal Segments in Urinary Diversion

Anton Wintner MD, Douglas M. Dahl MD, FACS

Reconstructive urologic surgery frequently requires the use of bowel for ureteral substitution, bladder augmentation, or bladder replacement. In rare cases, gastrointestinal segments may also function as urethral or vaginal substitutes. The stomach, jejunum, ileum, and colon all have a role in urinary tract reconstruction. This chapter reviews the surgical anatomy and technical aspects involved in the use of intestinal segments in urologic surgery that pertain to all types of reconstructive procedures and describes the important potential acute and long-term complications of the use of intestinal segments.

Surgical Anatomy

The most frequently used segments of bowel by the urologist are the ileum and colon. The stomach, jejunum, and rectum are also used in reconstructive procedures, although less commonly. Successfully performing surgical mobilization of these structures and reconstructing them for their new function requires a thorough knowledge of the surgical anatomy, vascular supply, and metabolic function of each portion of the intestinal tract.

Stomach

The stomach is a vascular organ that receives its blood supply primarily from the celiac trunk (Fig. 139.1). **Three branches of the celiac axis give rise to the majority of the arterial supply of the stomach.**

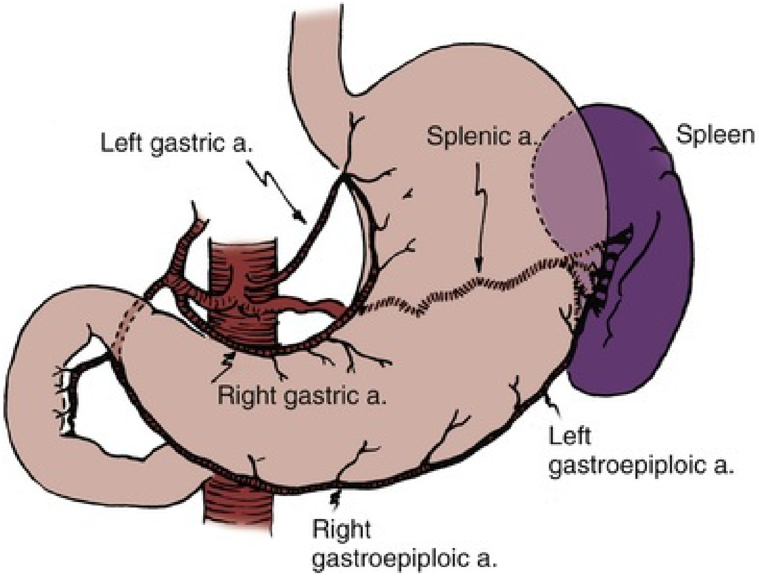

FIG. 139.1 Arterial supply of the stomach. *a,* Artery.

1. The **left gastric (coronary) artery** arises directly from the celiac axis and supplies the lesser curvature.
2. The **hepatic artery,** after arising from the celiac axis, **gives off the right gastric artery,** which also supplies the lesser curve of the stomach, and the **gastroduodenal artery,** which supplies the antrum and duodenum

before giving off the **right gastroepiploic artery.**

3. The **splenic artery** originates from the celiac axis and gives off the **vasa brevia (short gastrics),** which supply the fundus and cardia, and the **left gastroepiploic artery.** The right gastroepiploic artery meets with the left gastroepiploic artery; thus both supply collateral flow to the greater curve of the stomach. **By use of the gastroepiploic vessels, a pedicle of stomach may be mobilized as far as the pelvis.** The pedicle may consist of the entire antrum pylori or a wedge of the fundus.

The blood supply for these segments is based on either the left or right gastroepiploic artery, depending on the portion of stomach used. On occasion, the left gastroepiploic artery is atretic at some point in its course and does not provide an adequate blood supply. Under these circumstances, the right gastroepiploic artery must be used. **When a wedge of fundus is used, it should not include a significant portion of the antrum and should never extend to the pylorus or all the way to the lesser curve of the stomach.** When the blood supply is based on the left gastroepiploic artery, the short gastric vessels that course from the gastroepiploic artery to the stomach are ligated along the greater curvature proximal to the pedicle to the origin of the gastroepiploic artery. The omentum is left attached to the gastroepiploic vessels and helps secure and support them. It may be necessary for proper pedicle mobility to detach the omentum from the colon along the avascular plane located at the point of its attachment to the transverse colon. If an antrectomy is performed, a Billroth I anastomosis reconstitutes gastrointestinal continuity. **The stomach has a thick seromuscular layer that can be easily separated from the mucosa should a submucosal ureteral reimplantation be necessary.**

Small Bowel

The small bowel is about 22 feet long; however, it may vary from 15 to 30 feet in length. Its largest diameter is in the duodenum; the lumen becomes smaller in the more distal portions, reaching its smallest diameter in the ileum, approximately 12 inches from the ileocecal valve. **About two-fifths of the small bowel is jejunum, whereas the distal three-fifths is ileum.**

There is no definite demarcation between the two; however, each possesses several unique properties that allow the surgeon to distinguish one from the other intraoperatively. **The ileum, being more distal in location, has a smaller**

diameter. It has multiple arterial arcades, and the vessels in the arcades are smaller than those in the jejunum. The ileal mesentery is also thicker than the jejunal mesentery. In contrast, the jejunal diameter is larger, the arterial arcades are usually single, and the vessels composing them are larger in diameter.

The arcades anastomose one with another and give off straight vessels, which enter the bowel and form an anastomotic network within the bowel wall. **It has been shown experimentally that up to 15 cm of small bowel can survive laterally to a straight vessel.** Thus, theoretically, the mesentery could be cleared from the small bowel for a length of 15 cm without necrosis of the end. **In general, however, it is unwise to assume that more than 8 cm of small bowel will survive away from a straight vessel.** The arcades receive their blood from the superior mesenteric artery. When segments of jejunum or ileum are isolated, the mesentery should be transected in such a way that the isolated intestinal segment receives its blood supply from an arcade supplied by a palpable artery of substance that courses through the base of the mesenteric pedicle.

Two portions of the small bowel may lie within the confines of the pelvis and, as such, may be exposed to pelvic irradiation and pelvic disease: **the last 2 inches of the terminal ileum,** which is often fixed in the pelvis by ligamentous attachments, **and the 5 feet of small bowel beginning approximately 6 feet from the ligament of Treitz,** the mesentery of which is the longest of the entire small bowel. As such, this portion of the small bowel can descend into the pelvis. **In a postirradiated patient, one should try to avoid use of these two segments of the small intestine in any reconstructive procedure.**

Colon

The large bowel is divided into the cecum, ascending colon, transverse colon, left colon, sigmoid colon, and rectum. Portions of the large bowel are fixed or retroperitoneal, and other segments lie free within the peritoneal cavity. The cecum, on rare occasion, may lie free within the abdominal cavity and therefore may have great mobility. In general, however, it is fixed in the right lower quadrant. Two accessory peritoneal bands bind the cecum and distal ileum to the retroperitoneum and lateral abdominal wall. One band arises from the distal ileum, attaches to the cecum, and is fixed to the retroperitoneum. A second band arises from the cecum and fixes the cecum to the posterior abdominal wall laterally. The remainder of the ascending colon is fixed to the right posterior abdominal wall at the level of the hepatic flexure, at which point the hepatocolic ligament secures this portion of the colon to the liver. The transverse colon lies free within the abdominal cavity and is fixed in the left upper quadrant at the splenic flexure by the phrenocolic ligament. The transverse colon is attached to the stomach by the gastrocolic omentum. The descending colon is fixed to the lateral abdominal wall; however, the sigmoid colon may or may not lie free within the abdominal cavity. The rectosigmoid colon's most cephalad portion is intraperitoneal, and at its distal, more caudad, portions, it becomes retroperitoneal and finally subperitoneal.

The colon receives its blood supply from the superior mesenteric artery, inferior mesenteric artery, and internal iliac arteries (Fig. 139.2). **The major arteries supplying the colon and rectum include the ileocolic, right colic, middle colic, left colic, sigmoid, superior hemorrhoidal, middle hemorrhoidal, and inferior hemorrhoidal arteries.** These arteries anastomose with one another to form the arc of Drummond and allow considerable leeway in mobilizing the colon. The middle colic artery arises from the first portion of the superior mesenteric artery and typically ascends the transverse mesocolon to the right of midline. The right colic artery usually arises just below the middle colic artery from the superior mesenteric artery and courses to the right colon. In some cases, the right colic artery may arise from the ileocolic artery or directly from the middle colic artery. If the right colic artery arises from the ileocolic artery, mobilization of a distal ascending colon segment is more likely to be brought easily into the deep pelvis. On occasion—particularly if the right colic artery originates from the middle colic artery—it is necessary to divide the right colic artery at its origin to mobilize the distal portion of the ascending colon to the pelvis. The ileocolic artery is the terminal portion of the superior mesenteric artery and supplies the last 6 inches of ileum and ascending colon. The left colic artery arises from the inferior mesenteric artery, and then the inferior mesenteric artery gives off four to six sigmoid branches, the last of which becomes the superior hemorrhoidal artery. This anastomoses with the middle hemorrhoidal artery, a branch of the internal iliac artery, which, in turn, anastomoses with the inferior hemorrhoidal artery, the terminal branch of the internal pudendal artery. The middle sacral artery, which originates directly from the aorta, may supply the posterior aspect of the rectum.

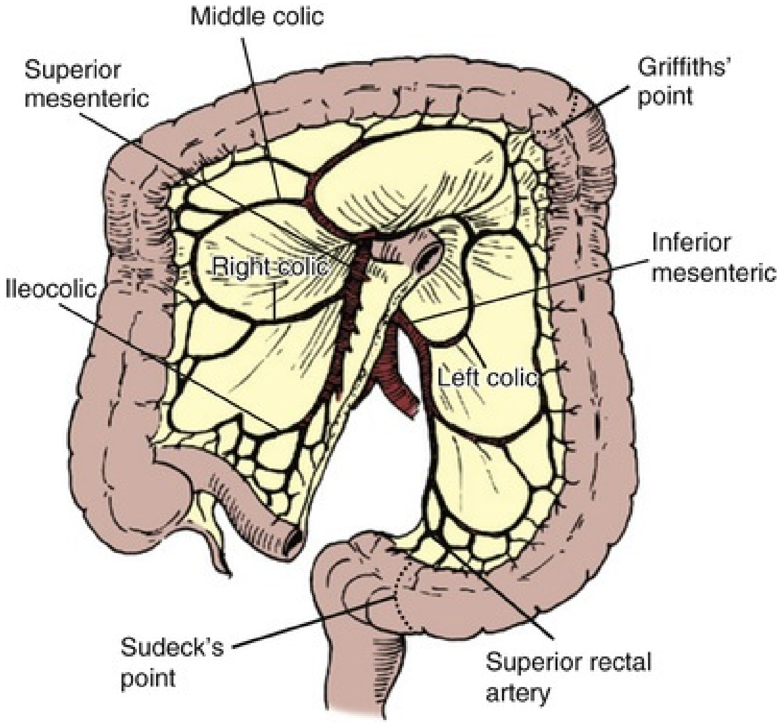

FIG. 139.2 Arterial supply and watershed areas of the small bowel and colon.

Watershed areas are regions of the colon that receive dual blood supply from the most distal branches of two larger arteries. Because of the small diameter of these distal branches, watershed areas are particularly vulnerable to ischemia in the setting of hypotension or thromboembolic event. Within the colon, two main watershed areas need to be considered. **Griffith's point, the collateral communication between the middle colic artery and the ascending left colic artery, is important for perfusion of the splenic flexure and descending colon.** Similarly, **Sudeck's point,** which is located between the junction of the last **sigmoid branch and superior hemorrhoidal artery,** is thought to be a tenuous anastomotic area such that if the colon were transected in this region, the blood supply to the anastomosis may be compromised (Sakorafas et al., 2006). Although anastomoses in these locations usually heal well provided the principles of proper technique are followed, if possible it is wise to select an area for the anastomosis to one side of these points, where the feeding arteries have a larger diameter.

The ascending colon is mobilized first by transecting the cecal and distal ileal fibrous attachments to the lateral abdominal wall and retroperitoneum as described earlier and then by detaching it from the lateral abdominal wall along the avascular line of Toldt. This is a bloodless plane, provided the colonic mesentery is not violated. The transverse colon is mobilized by dividing the gastrocolic omentum (along the avascular plane of its attachment to the colon), the hepatocolic ligament (which may have some small vessels coursing through it), and the phrenocolic ligament. The descending colon is mobilized, much like the right colon, by incision of the avascular line of Toldt lateral to the colon. With these attachments taken down, there is considerable mobility of the colon. Further mobility is gained by isolating a pedicle of the intestinal segment on the basis of one of the major arterial vessels described earlier.

Key Points

- No more than 8 cm of mesentery should be cleared from the end of a small bowel segment to allow for adequate perfusion and minimize the risk for necrosis.
- Two main watershed areas are found in the colon where, if possible, anastomosis should be avoided: Griffith's point near the splenic flexure (middle colic artery and left colic artery) and Sudeck's point near the rectosigmoid junction (most inferior sigmoidal branch and superior rectal artery).

Selecting the Segment of Intestine

The stomach, jejunum, ileum, and colon have unique properties, each of which has special advantages and disadvantages. The selection of the proper intestinal segment should be based on the patient's condition, renal function, history of previous abdominal procedures, and type of diversion or substitution required.

Stomach

The stomach has been used as a replacement for bladder, for augmentation cystoplasty, as a conduit, and for continent diversions (Abdel-Azim and Abdel-Hakim, 2003; Bissada et al., 2004; Castellan et al., 2012; DeFoor et al., 2003). **The advantages of the stomach over other intestinal segments for urinary intestinal diversion are that it is less permeable to urinary solutes, it has a net excretion of chloride and protons rather than a net absorption of them, and it produces less mucus.** Urodynamically, it behaves as other intestinal segments do. When it is used in urinary reconstruction, electrolyte imbalance rarely ensues in patients with normal renal function, although **hypochloremic metabolic alkalosis** has been described. The incidence of bacteriuria has been reported to be as low as 25%, much less than the 60% to 80% incidence reported for ileal and colon segments. However, more recent data suggest that there is no difference in bacteriuria among any of the segments. The urine, which usually has a pH of 6 to 7, does not typically result in an increased incidence of peristomal skin problems. Authors have also noted that in bladder augmentation patients, there is little difference in urinary pH between gastric and ileal augmentations. Serum gastrin levels are usually normal or minimally elevated, depending on what portion of the stomach is used and how much (Adams et al., 1988; Leong, 1978). Experimentally, antral exclusion may result in elevated circulating gastrin levels, leading to intestinal ulcerative problems in the postoperative period (Tiffany et al., 1986).

Rarely, severe ulcerative complications have occurred in cases in which stomach has been used for urinary reconstruction (Reinberg et al., 1992; Tainio et al., 2000)**. Long-term histamine (H_2 receptor) antagonists or proton-pump inhibitors should be considered for these patients.** The antrum should not be used if the fundus is available. If the antrum is used, reconstitution is generally by a Billroth I anastomosis. Complications with Billroth I gastroduodenostomy are well documented.

Early complications of the use of portions of the stomach for reconstruction include gastric retention caused by atony of the stomach or edema of the anastomosis; hemorrhage, most commonly originating from the anastomotic site; hiccups secondary to gastric distention; pancreatitis as a consequence of intraoperative injury; and duodenal leakage. Delayed complications include dumping syndrome, steatorrhea, small stomach syndrome, increased intestinal transit time, bilious vomiting, afferent loop syndrome, hypoproteinemia, and megaloblastic or iron deficiency anemia. Some studies report postoperative bowel obstruction has to be as high as 10% (2 of 21 patients) in adults (Leong, 1978), only a rare complication in pediatric patients (DeFoor et al., 2003; Mingin et al., 1999). Gastroduodenal and gastroureteral leaks have also been reported, occasionally resulting in a fatal outcome (Leong, 1978).

The use of stomach for urinary intestinal diversion may be considered in patients with severe renal dysfunction who would be unable to tolerate metabolic acidosis and those with the potential for short gut syndrome, in whom use of other intestinal segments would result in serious nutritional problems. One advantage of using stomach segments in the patient with severe abdominal adhesions is that the area of the stomach is, in general, adhesion free and easily mobilized.

Other **complications specific to the use of stomach include the hematuria-dysuria syndrome** in approximately 24% of patients (Castellan et al., 2012). Symptoms of hematuria-dysuria syndrome include bladder spasms; suprapubic, penile, or periurethral pain; gross hematuria without infection; skin excoriation; or dysuria without infection (Chadwick Plaire et al., 2000). These symptoms are typically intermittent and self-limiting, and can usually be controlled with H_2 blockers. The etiology is believed to be a result of the production of acid by the gastric segment, however, the symptoms have been seen even with urine acidity in the normal range (Aponte et al., 2015).

Severe metabolic alkalosis associated with respiratory distress has also been seen in some patients' gastric augments or conduits (see the Metabolic Complications section later in this chapter).

Jejunum

The jejunum is usually not used for reconstruction of the urinary system because it may result in severe electrolyte imbalance, most concerningly

hyperkalemia. In general, diseases that would make the ileum inappropriate for use also make the jejunum inappropriate for use. Rarely, it is the only segment available. Under these circumstances, as distal a segment of jejunum as possible should be used to minimize the electrolyte problems.

Ileum and Colon

The ileum and colon are used most often for urinary tract reconstruction and have been used in all types of reconstructive procedures. The ileum is mobile and of small diameter, has a constant blood supply, and serves well for ureteral replacement and the formation of conduits. **Loss of significant portions of the ileum results in nutritional problems because of lack of vitamin B_{12} absorption, diarrhea because of lack of bile salt reabsorption, and fat malabsorption.** On occasion, the mesenteric fat is excessive, making mobility and anastomosis difficult. Also, the mesentery may be so short that it is difficult to mobilize the ileum into the deep pelvis. **Postoperative bowel obstruction occurs in up to 10% of patients who have segments isolated from the ileum for urinary tract reconstruction** (Varkarakis et al., 2007). As many as one-half of the obstructions occur in the early postoperative period (Schwarz and Jeffs, 1975).

The colon requires mobilization from its fixed positions to give it the mobility necessary for use in urinary reconstruction. It has a larger diameter than the ileum and is usually easily mobilized into any area of the abdomen or pelvis. In patients who have received pelvic irradiation, portions of the right, transverse, and descending colon may be used confidently with the knowledge that they have not been exposed to the radiation therapy. Removal of segments of colon from the enteric tract results in fewer nutritional problems than does removal of segments of ileum, provided the ileocecal valve is not violated. Should the ileocecal valve be used, diarrhea, excessive bacterial colonization of the ileum with malabsorption, and fluid and bicarbonate loss may occur. **With colon, the incidence of postoperative bowel obstruction requiring reoperation is 5%, about one-half the incidence of ileum.** Both ileal and colon segments result in the same type of electrolyte imbalance with similar frequencies. **An antireflux ureterointestinal anastomosis by the submucosal tunnel technique is easier to perform with use of the colon.** In general, ileum and colon are comparable and have few differences, which does not argue strongly for the selection of one over the other except under special circumstances.

Key Points

- The use of stomach is associated with ulcerative complications and hematuria-dysuria syndrome, but has the advantage of a net excretion of H^+ and Cl^-.
- The use of jejunum may result in severe electrolyte imbalance, most concerningly hyperkalemia, and should thus be avoided if possible.
- Exclusion of significant portions of the ileum can result in vitamin B_{12} deficiency and decreased bile salt reabsorption.
- There is a lower rate of postoperative bowel obstruction requiring reoperation colon versus ileal urinary diversion.

Preparing the Bowel for Surgery and Postoperative Recovery

Complications that result from bacterial contamination are a major cause of morbidity and mortality in patients undergoing urologic procedures. In experimental animals, it has been shown that an anastomosis with vascular compromise at the anastomotic line, which would normally result in perforation, heals if the bowel has been properly prepared with antibiotics. Additionally, solid feces may place strain on the anastomosis in the early phase of healing and result in ischemia with subsequent perforation and intra-abdominal or wound infection.

In 1981, Bracken et al. reported that infectious complications after radical cystectomy that are the direct result of fecal contamination may occur in 18% to 20% of patients. These include wound infections, peritonitis, intra-abdominal abscesses, wound dehiscence, anastomotic dehiscence, and systemic sepsis. More recent series suggest that current management practices have made a substantial improvement, with perioperative infectious complications of 7% (Månsson et al., 2003; Stein et al., 2004). A series of 359 patients found infectious complications in 11.1% (Berneking et al., 2013).

It has been a long-held tenet of elective intestinal surgery that bowel preparation is beneficial. The bacterial population in the stomach is relatively low, but in the remaining segments of the bowel including the jejunum, ileum, and colon, there are high bacterial counts. Early studies suggested that bowel anastomoses in patients whose intestinal tract had not been prepared before surgery had increased wound infection rates, increased intraperitoneal abscesses, and an anastomotic dehiscence rate greater than in patients who received proper bowel preparation before surgery (Dion et al., 1980; Irwin and Goligher, 1973). Other studies have shown that mechanical preparation resulted in collapsed bowel at the time of surgery, which was shown to reduce the incidence of anastomotic leaks (Christensen and Kronborg, 1981).

Studies have recently begun to question the widely held belief that bowel preparation is mandatory. In meta-analyses of randomized clinical trials of anastomotic leakage during colon and rectal surgery, researchers found that there was no support for the conclusion that mechanical bowel preparation reduces anastomotic leak rates and other complications in elective open colon surgery

(Güenaga et al., 2011). **Several small randomized studies in patients undergoing cystectomy with ileal conduit urinary diversion have shown no difference in infectious complications between the groups of patients who received bowel preparation and those who did not** (Hashad et al., 2012; Xu et al., 2010). Notably, these studies excluded patients with a history of radiotherapy, immunosuppression, antibiotic administration within 1 preparative week, and liver or renal dysfunction.

There are two aspects to bowel preparation: mechanical and antibiotic. Both methods attempt to reduce the complication rate from intestinal surgery. **Mechanical preparation reduces the amount of feces (and therefore the total number of bacteria), whereas antibiotic preparation reduces the bacterial count per gram of feces (concentration).** The bacterial flora in the bowel consists of aerobic organisms, the most common of which are *Escherichia coli* and *Enterococcus faecalis*, and anaerobic organisms, the most common of which are *Bacteroides* species and *Clostridium* species. **The bacterial concentration ranges from 10 to 10^5 organisms per gram of fecal content in the jejunum, 10^5 to 10^7 in the distal ileum, 10^6 to 10^8 in the ascending colon, and 10^{10} to 10^{12} in the descending colon.**

Mechanical Bowel Preparation

Mechanical bowel preparation reduces the total number of bacteria but not their concentration. There is no change in the number of organisms present per gram of fecal content (Nichols et al., 1972). Therefore spilling enteric contents during the procedure may be less likely with the mechanically prepared bowel because there is less of it to spill; however, once spilled, cubic centimeter for cubic centimeter, the inoculum is the same as if the bowel had not been prepared. Some analyses even suggest that there may be an increase in bacterial contamination in patients who have undergone bowel preparation (Fa-Si-Oen et al., 2005), perhaps caused by decreased stool viscosity postprep.

Conventional bowel preparations commonly used in the past tended to exhaust the patient and exacerbate nutritional depletion because they typically required a 3-day preparation period of insufficient calorie intake (Table 139.1). The use of elemental diets has been advocated to clean the colon of feces while not compromising the nutritional status of the patient. Unfortunately, this has not proven useful because the elemental diets do not empty the colon of feces, and they do not reduce the bacterial flora (Arabi et al., 1978). In an attempt to reduce the time required for intestinal preparation and to obviate low-calorie intakes, whole-gut irrigation has been used. Originally, whole-gut irrigation was performed by placement of a nasogastric tube (NGT) into the stomach and infusion of 9 to 12 L of lactated Ringer's solution or normal saline during a several-hour period. These fluids were subsequently replaced with 10% mannitol, which was equally successful in ridding the bowel of its fecal content; however, the mannitol served as a bacterial nutrient and thereby facilitated microbial growth (Hares and Alexander-Williams, 1982). These solutions have largely been replaced by a polyethylene glycol (PEG)–electrolyte solution.

TABLE 139.1

Mechanical Bowel Preparation

PREOPERATIVE		CONVENTIONAL	POLYETHYLENE GLYCOL–ELECTROLYTE SOLUTIONS	
DAY	DIET	CATHARTIC	DIET	POLYETHYLENE GLYCOL
3	Low residue plus supplements		Regular plus supplements	
2	Low residue plus supplements		Low residue plus supplements	
1	Clear liquids	10 oz citrate of magnesia over 2 h at 1 pm	Clear liquids	2–4 L (adults) or 25 mL/kg/h × 2 h (do not exceed 2 L in children)

Whole-gut irrigation may be exhausting to the patient and may, in fact, result in a fluid gain, particularly when either saline or mannitol is used. **Whole-gut irrigation is contraindicated in patients with an unstable cardiovascular system, cirrhosis, severe renal disease, congestive heart failure, or an obstructed bowel.** Whole-gut irrigation has been found to be no more effective than conventional preparations in reducing wound infections and septic complications (Christensen and Kronborg, 1981), even though there is a reduction of aerobic flora compared with conventional preparations (van den Bogaard et al., 1981). **The advantages of whole-gut irrigation are that it gives the patient dietary freedom, there is a short preparation time, and it eliminates an enema. Its disadvantages are that it may result in the patient's exhaustion, it is rather rigorous, and it does result on occasion in fluid**

overload.

The PEG-electrolyte lavage solutions (e.g., GoLYTELY or the more palatable NuLYTELY) are effective lavage agents in preparing the gut. For the adult, 20 to 30 mL/min or approximately 1 to 1.5 L/h for 3 hours is given either orally or through a small-caliber NGT placed into the stomach. If it is taken by mouth, it is better tolerated if the solution is chilled. The administration of PEG lavage is stopped when the rectal effluent is clear and there is no particulate matter in it or when 4 L of fluid has been given. The septic complications with its use are approximately 4%. An inadequate preparation occurs in 5% of the patients using this modality (Wolff et al., 1988). For children, even those younger than 1 year of age, PEG lavage may be used at a rate of 20 to 40 mL/kg/h and given until the rectal effluent is clear and free of particulate matter (Tuggle et al., 1987). Metoclopramide, 10 mg in adults, is often given simultaneously to control nausea.

Oral cathartic bowel preparation is another acceptable strategy for reducing fecal burden before intestinal surgery. Oral solutions of magnesium citrate or sodium phosphate are both effective in cleansing the intestinal tract (Borden et al., 2010). The volume of fluid the patient must consume is substantially lower (148 mL MagCitrate and 45 mL NaPhosphate), and the preparations are typically well tolerated in healthy patients.

Bowel preparation can increase metabolic complications and cause electrolyte disturbances, which could affect surgical care. **Caution must be exercised in elderly and debilitated patients receiving sodium phosphate preparation; the sodium phosphate preparation has been shown to cause significant derangements in potassium, calcium, and phosphorus levels in frail individuals** (Beloosesky et al., 2003)**. Phosphate nephropathy has been recognized as a serious complication of oral sodium phosphate (OSP) bowel preparation** (Markowitz et al., 2005)**. Caution should be used in prescribing OSP to patients with underlying renal insufficiency or those being treated with nephrotoxic medications.** In the United States, OSP was recently changed to prescription only by the US Food and Drug Administration (FDA). **OSP should rarely be used.** The only study in postsurgical complications comparing sodium phosphate with PEG found no significant difference in complication rates (Oliveira et al., 1997). One study suggested that PEG is better tolerated by elderly patients and causes less disruption in potassium and sodium levels (Seinelä et al., 2003). Oral electrolyte solution rehydration may prevent some of the complications of bowel preparation (Tjandra and Tagkalidis, 2004).

A number of studies have questioned the efficacy of mechanical bowel preparation. Some have suggested that a limited mechanical bowel preparation is all that is necessary; others have questioned even the need for a mechanical bowel preparation. In one study, 2 L of PEG plus metoclopramide was compared with the administration of 4 L of PEG solution. There was no difference in surgical complication rate or the extent to which the bowel was clean (Gründel et al., 1997). In another study, when 4 L of PEG was compared with 90 mL of sodium phosphate, there was no significant difference in surgical complication rate (Oliveira et al., 1997). Two meta-analyses have found that there is an increased anastomotic dehiscence rate with preoperative mechanical bowel preparation (Bucher et al., 2005; Wille-Jørgensen et al., 2003). PEG may be the agent responsible for the increased rate of complications, but other preparation strategies have not been adequately analyzed. A meta-analysis of randomized trials comparing mechanical bowel preparation with no bowel prep before elective colorectal surgery found no difference between the groups for anastomotic leakage, abdominal abscess, or wound sepsis (Slim et al., 2009). **No study has adequately addressed the issue of the need for debulking of the intestine before laparoscopic approaches to intestinal surgery.** It is extremely important to note that in these studies, the administration of intravenous antibiotics was crucial in keeping the complication rate low. **Moreover, it is important to note that in these studies there was limited exposure of the intestine because the patients underwent elective bowel resections, unlike urologic procedures in which long segments of the intestine are opened or interposed in a urinary tract that is normally free of fecal contents.**

Antibiotic Bowel Preparation

There has been considerable controversy as to whether the addition of oral antibiotics in elective colon and small bowel surgery reduces mortality and morbidity significantly. **The long-held practice of mechanical and oral antibiotic bowel preparation dates to the 1970s.** In one study, the septic complication rate was reduced from 68% in the control group to 8% in the antibiotic group (Washington et al., 1974). Most series, however, report a lesser incidence of reduction in wound infection, in general from 35% without antibiotics to 9% with their use (Clarke et al., 1977). Others have suggested that the mortality rate drops from 9% to 3% with the use of antibiotics (Baum et al., 1981). It is clear that the use of antibiotics protects vulnerable bowel in that it may allow the tenuous anastomosis to survive.

Other studies, however, have shown that without the use of oral antibiotics in mechanically prepared bowel in elective surgery, the septic complication rate is comparable with that in those studies using antibiotics, and the rate of *Clostridium difficile* colitis is lower without oral antibiotics (Wren et al., 2005). In the presence of a bowel obstruction, however, oral antibiotics are of little value because they do little good in sterilizing the bowel. **The disadvantages of antibiotics may include postoperative increase in the incidence of diarrhea; pseudomembranous enterocolitis; theoretically increased incidence of tumor implantation at the suture line that is not germane to urologic surgery; monilial overgrowth resulting in stomatitis, thrush, and diarrhea; and, with prolonged use, malabsorption of protein, carbohydrate, and fat.** The antibiotics most commonly used for bowel preparation include kanamycin, which is the best single agent; neomycin and erythromycin base; and neomycin and metronidazole (Table 139.2). With an appropriate antibiotic preparation, enteric organisms are reduced to 10^2 per gram of feces (Nichols et al., 1972). **A contemporary randomized trial of patients undergoing elective colonic surgery found the lowest fecal bacterial concentrations when patients had preoperative mechanical bowel preparation, oral neomycin, and supplemental "synbiotic" treatment (to provide benign flora to the intestine).** No difference in clinical infections was seen between patients prepared with or without oral antibiotic bowel preparation (Reddy et al., 2007). A large series of 2475 patients from Michigan **undergoing colon surgery showed lower infection (5.0% vs. 9.7%) and less *C. difficile* colitis (0.5% vs. 1.8%) with mechanical and oral antibiotic bowel preparation** (Kim et al., 2014). Most recently, a retrospective cohort study of 89 patients undergoing left colon and rectal cancer resection demonstrated that **the addition oral antibiotics (neomycin and metronidazole) to mechanical bowel prep (magnesium citrate) decreased the rate of surgical site infection (SSI) from 27% to 8% ($P = 0.03$) versus mechanical bowel prep alone.** In addition, the patients who received an oral antibiotic prep had a decreased rate of organ space infections (0% vs. 18%; $P = 0.004$) and anastomotic leaks (0% vs. 10%; $P = 0.06$). Both groups in the study received perioperative intravenous antibiotics and skin prep with chlorhexidine (Vo et al., 2018)

TABLE 139.2

Antibiotic Bowel Preparation

PREOPERATIVE DAY	**KANAMYCIN**	**NEOMYCIN PLUS ERYTHROMYCIN BASE**	**NEOMYCIN PLUS METRONIDAZOLE**
3	1 g kanamycin orally every 1 h × 4, then 4 times/day	—	—
2	1 g kanamycin orally 4 times/day	—	1 g neomycin 4 times/day plus 750 mg metronidazole 4 times/day
1	1 g kanamycin orally 4 times/day	1 g erythromycin base plus 1 g neomycin at 1 pm, 2 pm, and 11 pm	1 g neomycin 4 times/day plus 750 mg metronidazole 4 times/day

Perioperative intravenous antibiotics appear to be the most important means of preventing infectious complications of intestinal surgery. Systemic antibiotics must be given before the operative event if they are to be effective. Ideally, antibiotics should be given between 1 and 2 hours before the start of surgery (Classen et al., 1992). They appear to be most effective against the anaerobic flora and apparently reduce the complications caused by these organisms (Dion et al., 1980). Perioperative systemic antibiotics, when added to the oral regimen, reduced the septic complication rate from 15% to 20% to 50% that rate in several series (Gottrup et al., 1985; Hares and Alexander-Williams, 1982). Other studies, however, have shown no effect of systemic cephalosporin, for example, in reducing septic complications (Wolff et al., 1988). **If perioperative antibiotics are given, they should be effective against anaerobes because it is complications from these organisms against which perioperative antibiotics appear to be particularly effective.** Third-generation cephalosporins have been advocated as an appropriate systemic antibiotic. Other recent studies support the use of both oral and systemic intravenous antibiotic prophylaxis before intestinal surgery (Kim et al., 2014). It is clear that preoperative antibiotics reduce postoperative complications. Most agree that preoperative intravenous antibiotics are important, and some advocate discontinuing the use of oral antibiotics out of concern for developing *C. difficile* diarrhea (Wren et al., 2005).

It is our preference to perform both a mechanical and an antibiotic bowel preparation. The patient is allowed a normal diet until 1 day preoperatively, at which time a clear liquid diet is begun and magnesium citrate is given as a cathartic. Oral antibiotic bowel preparation with neomycin is also prescribed. Preoperative hydration with a sports beverage is continued until 2 hours before surgery. On the day of surgery, the patient is given intravenous antibiotics 1 hour before the incision as recommended by AUA guidelines.

The AUA guidelines for antibiotic prophylaxis in patients undergoing urinary diversion are summarized in Table 139.3 (Wolf et al., 2008).

TABLE 139.3

AUA Guidelines for Antibiotic Prophylaxis in Patients Undergoing Urologic Surgery Involving Intestine

PROPHYLAXIS RECOMMENDED FOR	PRIMARY CHOICE	ALTERNATIVES
All patients undergoing urologic surgery involving the intestine[a–c]	Second- or third-generation cephalosporin or Aminoglycoside + metronidazole or clindamycin	Ampicillin/sulbactam Ticarcillin/clavulanate Piperacillin/tazobactam Fluoroquinolone

[a] For surgery involving the colon, bowel preparation with oral neomycin plus either erythromycin base or metronidazole can be added to or substituted for systemic agents.

[b] Prophylaxis should be limited to 24 hours after a procedure unless (1) prosthetic material is placed, (2) an external urinary catheter is placed before or at the time of the procedure in patients with certain risk factors, or (3) the patient has documented bacteriuria.

[c] First dose of antibiotics should be given within 60 minutes of surgical incision (or 120 minutes in the case of vancomycin or fluoroquinolones)

Diarrhea and Pseudomembranous Enterocolitis

Bowel preparations may result in diarrhea and pseudomembranous enterocolitis. Pseudomembranous enterocolitis is the more severe form of a spectrum of diarrhea. Clinically, this occurs after a bowel preparation in the postoperative period and is heralded by abdominal pain and diarrhea, usually in the absence of fever or chills. As the symptoms and infection become more severe, systemic toxicity supervenes. **These patients can develop a toxic megacolon, and if this occurs, the mortality may exceed 15% to 20%.** Historically, pseudomembranous enterocolitis was thought to be caused by *Staphylococcus*, but there was, in fact, little evidence to support that organism as the causative agent. It is now clear that ***C. difficile* plays a significant role in the majority of cases.** *C. difficile* elaborates at least two toxins that cause diarrhea and enterocolitis. *C. difficile* does not invade the bowel, and it is not normally a significant inhabitant of the fecal flora. It is held in check by other bacteria that inhibit its growth. Thus antibiotics destroy the bacteria that inhibit the growth of *C. difficile* and thereby allow it to flourish. The toxin produces a diffuse inflammatory response with cream-colored plaque formation, erythema, and edema of the bowel wall. On microscopic examination, the villi appear to be intact, and there is a polymorphonuclear leukocyte infiltrate of the submucosa (Bartlett, 2002).

As the disease progresses, large areas of the bowel are denuded of their mucosa, which may slough. The lesions may involve the colon, in which case it is called *pseudomembranous enterocolitis*, or the small bowel, in which case it is called *pseudomembranous enteritis*, or they may involve both.

The diagnosis may be suspected from symptoms or endoscopy and is confirmed by culture of the organism or identification of its toxin. According to the American Society of Gastroenterology guidelines, only stool from patients with diarrhea should be tested. **Nucleic acid amplification tests (NAATs) for *C. difficile* toxin genes** such as PCR are superior to toxins A + B enzyme immunoassay (EIA) tests because of improved sensitivity and specificity. Repeat testing, and testing for cure are discouraged (Surawicz et al., 2013).

Once the diagnosis has been made, **treatment involves the administration of vancomycin or metronidazole and discontinuance of other antibiotics that the patient is receiving.** Vancomycin or metronidazole is effective in most cases. **Rarely, toxic megacolon supervenes, necessitating subtotal colectomy as a lifesaving procedure** (Chang, 1985). Newer therapy with antibodies to the toxin hold promise in reducing the morbidity of the disease (Lowy et al., 2010). A summary of management recommendations by the American Society of Gastroenterology can be found in Table 139.4 (Surawicz et al., 2013).

TABLE 139.4

C. difficile Severity Scoring System and Summary of Treatments

SEVERITY	CRITERIA	TREATMENT	COMMENT
Mild to	Diarrhea + other	Metronidazole 500 mg PO	If no improvement

moderate	signs or symptoms not meeting criteria for severe or complicated	TID × 10 days; if unable to take, then vancomycin 125 mg PO QID × 10 days	after taking metronidazole for 5–7 days, then switch to vancomycin for 10 days
Severe	Albumin <3g/dL Plus ONE of: WBC >15,000 cells/mm^3 *or* abdominal tenderness	Vancomycin 125 mg PO QID × 10 days	
Severe and complicated	Any of: ICU admission Hypotension Fever >38.5°C Ileus or significant abdominal distention WBC >35,000 or <2000 cells/mm^3 Serum lactate >2.2 mmol/L End organ failure	Vancomycin 500 mg PO QID and metronidazole 500 mg q8h and vancomycin PR (500 mg in 500 mL of saline as enema QID)	Surgical consultation
Recurrent	Within 8 weeks of completion of therapy	Repeat vancomycin or metronidazole pulse regimen	Consider fecal microbiota transplant after three recurrences

Enhanced Recovery After Surgery

Enhanced recovery after surgery (ERAS) protocols (also referred to as “enhanced recovery programs” or “fast-track protocols”) are evidence-based, collaborative perioperative care pathways designed to improve recovery after major surgical procedures. They aim to maintain preoperative organ function and reduce the body's stress response after surgery. ERAS protocols contain preoperative, intraoperative, and postoperative components that include patient counseling, nutritional optimization, standardized analgesic and anesthetic regimens, and early mobilization (Melnyk et al., 2011). Many protocols have also discontinued the use of a bowel prep as standard practice.

ERAS first gained traction in the 1990s in the field of colorectal surgery based on ideas put forth by Henrik Kehlet. Since then, adoption of ERAS protocols has increased as the evidence supporting their use has grown. Meta-analyses of studies of colorectal surgery patients have provided level 1 evidence for reduction of complications (50%) and hospital stay (2.5 days) by application of ERAS pathways (Varadhan et al., 2010). This has led to adoption of modified ERAS protocols in many surgical specialties including gynecologic, thoracic, vascular, pediatric, and orthopedic surgery, and most recently urology.

In urology, the best studied ERAS protocols are in patients undergoing radical cystectomy and urinary diversion. Bowel complications are thought to account for the majority of extended hospital stays in this patient population with postoperative ileus (POI) being the most common complication (Chang et al., 2002). One difference between urology and colorectal surgery is that **radical cystectomy patients are believed to be at higher risk for POI compared with the colectomy population** because of deperitonealization of the pelvis for extended periods during pelvic lymphadenectomy, exposure of the bowel to urine, longer operative times, an older patient population with a higher incidence of comorbid conditions, and a higher smoking rate resulting from the association of smoking with urothelial cancer (Ramirez et al., 2013).

The precise definition of POI varies from study to study, but usually consists of a prolonged inability to tolerate oral intake without evidence of bowel obstruction. Several trials have examined the effect of implementation of ERAS protocols in patients undergoing radical cystectomy. In general, the evidence appears to support implementation of ERAS protocols for well-selected patients, though study results are difficult to compare directly given the variability in protocols and end points between studies (Azhar et al., 2016). In addition, cultural factors, differences in patient expectations, and health-care reimbursement structure can affect end points such as length of stay, time to resumption of regular diet, and patient satisfaction.

Arumainayagam et al. studied the implementation of an ERAS protocol in radical cystectomy patients (Arumainayagam et al., 2008). In this study, 56 consecutive non-ERAS patients were compared with 56 consecutive patients immediately after implementation of an ERAS protocol. Readmission, mortality, and morbidity rates were not significantly different between the groups. The length of stay, however, was reported to be 4 days shorter in the ERAS group (13 vs. 17). Another trial compared 26 consecutive non-ERAS patients to 51 ERAS patients and demonstrated similar findings, with a decreased length of stay in the ERAS group (10.4 days vs. 11.5 days) and no significant increase in complication or readmission rate (Mukhtar et al., 2013).

Shorter length of stay also has been demonstrated with the addition of alvimopan to the ERAS protocol. Alvimopan, a peripherally acting μ-opioid receptor antagonist, accelerates upper and lower gastrointestinal recovery and is indicated after surgeries that include bowel resection (Ludwig et al., 2008). **It acts by binding peripheral μ-opioid receptors in the gastrointestinal tract, preventing the binding of opioids with a subsequent decrease in associated bowel complications including slowed motility. Alvimopan has limited ability to cross the blood-brain barrier, which therefore allows for binding of opioids to μ-opioid receptors in the central nervous system for pain control** (US FDA, 2013).

Lee et al. conducted a randomized double-blind placebo-controlled trial in patients undergoing radical cystectomy and receiving postoperative intravenous patient-controlled opioid analgesics. Patients were randomized to alvimopan (n = 143) or placebo (n = 137). A modified intention-to-treat analysis demonstrated a quicker recovery of bowel function (5.5 vs. 6.8 days), shorter mean length of stay (7.4 vs. 10.1 days), and fewer episodes of postoperative ileus–related morbidity (8.4% vs. 29.1%) in the Alvimopan group (Lee et al., 2014). Alvimopan is only FDA approved for inpatient use only. The standard dosing protocol is 12 mg, 30 minutes to 5 hours before surgery then twice per week beginning the day after surgery until return of bowel function, or up to 7 days (15 total doses) (US FDA, 2013).

Despite these apparent successes, the implementation of ERAS protocols has not universally resulted in quicker return of bowel function and decreased length of stay. Saar et al. (2013) compared 31 consecutive patients on an ERAS pathway to 31 consecutive non-ERAS patients undergoing robotic-assisted laparoscopic radical cystectomy and found significantly decreased opioid use and time to regular diet in the ERAS group, but no difference in the time to bowel movement or length of stay. Similarly, Karl et al. (2014) prospectively randomized 101 consecutive patients to an ERAS (62) or non-ERAS (39) regimen. No significant difference in length of stay or time to bowel movement was noted, though time spent in the ICU appeared to be shorter in the ERAS group by 0.8 days. Interestingly, quality of life parameters as measured by the EORTC (European Organization for the Research and Treatment of Cancer) Quality of Life questionnaire (QLQ-30) did not change significantly between postoperative days 3 and 7 and discharge from hospital in the non-ERAS group, whereas a significant improvement was observed in the ERAS, suggesting that ERAS protocols may improve patient quality of life in the immediate postoperative period.

Several studies looked at the effect of specific components of the ERAS protocol. Pruthi et al. (2010) examined a 7-year experience with an ERAS pathway encompassing 362 consecutive cystectomy patients. Over time, the group altered their ERAS protocol and found the addition of chewing gum and metoclopramide to be beneficial in promoting return of bowel function. Of the 100 most recent patients in the series, 79% were discharged by postoperative day 5.

In a study of 107 patients on an ERAS protocol, Maffezzini et al. (2008) were able to demonstrate early return of flatus (POD 2) and regular diet (POD 4). Interestingly, neither early enteral nutrition nor early reinstitution of a regular diet prevented postoperative protein depletion as assessed by serum levels of total proteins, albumin, and lymphocyte count. This suggests that **even with early enteral nutrition, postoperative nutritional deficiencies are not likely to normalize in the early postoperative period.**

Table 139.5 summarizes the findings from published trials pertaining to the use of ERAS protocols for patients undergoing radical cystectomy, including several not mentioned here (Daneshmand et al., 2014; Dutton et al., 2014).

TABLE 139.5

Summary of Findings from Published Trials Pertaining to the Use of Enhanced Recovery After Surgery (ERAS) Protocols for Radical Cystectomy

STUDY	FINDINGS			
	LENGTH OF STAY	COMPLICATIONS	READMISSIONS	MORTALIT RATES
Arumainayagam	Median time	No significant	No significant	No significar

et al., 2008	significantly shorter for ERAS group by 4 d	difference in total complications between ERAS and control groups (ERAS n = 18; control n = 23)	difference between ERAS and control groups (ERAS n = 3; control n = 5)	difference between ERA and control groups (each group n = 1)
Pruthi et al., 2010	79% discharged on postoperative days 4–5[a]	39%[a]	2%[a]	0.01%[a]
Maffezzini et al., 2008	Not reported	35.3%[a]	Not reported	2.9%[a]
Mukhtar et al., 2013	Median time significantly shorter for ERAS group by 1.1 d	No significant difference between ERAS and control groups (ERAS n = 20; control n = 11)	0% for both groups	3 patients tot across group

Saar et al., 2013	No significant difference between ERAS and control groups (ERAS *M* = 18.0 d; control *M* = 18.1 d)	No significant difference in total complications between ERAS and control groups (ERAS *n* = 12; control *n* = 15)	No significant difference between ERAS and control groups (ERAS = 19.4%; control = 6.4%)	ERAS group = 1

Daneshmand et al., 2014	*M* = 4 d	65%[a]	21%[a]	1%[a]
Dutton et al., 2014	Mean = 9.2 d[a]	Complications rate was 6.6% for Clavien 3 and 43.5% for Clavien 2[a]	13.9%[a]	1.3%[a]
Karl et al., 2014	No significant difference in general LOS between groups; ICU time significantly shorter for ERAS group by 0.8 d	No significant difference in complications between groups	NR	0% in both groups

Lee et al., 2014 (alvimopan vs. placebo)	ERAS group shorter mean LOS (7.4 vs. 10.1 d)	Incidence of opioid consumption and AEs or serious AEs (SAEs) was comparable, except for POI, which was lower in the alvimopan group (AEs: 7% vs. 26%; SAEs: 5% vs. 20%)	30-day all-cause readmissions: alvimopan = 23.8% vs. placebo = 26.9% (NS)	Alvimopan = 3.5% vs. placebo = 2.9% (NS)

AE, Adverse event; *BM,* bowel movement; *d,* days; *ICU,* intensive care unit; *IV,* intravenous; *LOS,* length of stay; *M,* median; *NG,* nasogastric; *NR,* not reported; *NS,* not significant; *POI,* postoperative ileus; *SAE,* serious adverse event.

Modified from Azhar RA, Bochner B, Catto J, et al. Enhanced recovery after urological surgery: a contemporary systematic review of outcomes, key elements, and research needs. *Eur Urol* 70:176–187, 2016.

The ERAS Society, the main society dedicated to the study of multimodal perioperative care pathways, has published guidelines that include 22 ERAS recommendations for patients undergoing radical cystectomy (Cerantola et al., 2013). Complete discussion of each recommendation is beyond the scope of this chapter, but all 22 recommendations are summarized in Table 139.6.

TABLE 139.6

Enhanced Recovery After Surgery (ERAS) Society Guidelines for Radical Cystectomy

SUMMARY OF EACH ERAS ITEM AND ITS RESPECTIVE LEVEL OF EVIDE RECOMMENDATION DERIVED FROM THE CYSTECTOMY AND THE COL			
ERAS RECOMMENDATION	**SUMMARY**	**SPECIFICS FOR CYSTECTOMY PATIENTS/UNKNOWNS**	**EVIDE CYSTE SURGE**
1. Preoperative counseling and education	Patients should receive routine dedicated preoperative counseling and education.	Surgical details, hospital stay and discharge criteria in oral and written form; stoma education; patient's expectations	NA/low
2. Preoperative medical	Preoperative	Correction of anemia and	NA/mod

optimization	optimization of medical conditions should be recommended. Preoperative nutritional support should be considered, especially for malnourished patients.	comorbidities; nutritional support; smoking cessation and reduction of alcohol intake 4 weeks before surgery; encouraging physical exercise	NA/mod
3. **Oral mechanical bowel preparation**	Preoperative bowel preparation can be safely omitted.	—	Moderat
4. Preoperative carbohydrates loading	Preoperative oral carbohydrate loading should be administered to all nondiabetic patients.	—	NA/low
5. Preoperative fasting	Intake of clear fluids until 2 h before induction of general anesthesia is recommended. Solids are allowed until 6 h before anesthesia.	—	NA/mod
6. Preanasthesia medication	Avoidance of long-acting sedatives.	—	NA/mod
7. Thrombosis prophylaxis	Patients should wear well-fitting compression stockings and receive pharmacologic prophylaxis with LMWH. Extended prophylaxis for 4 weeks should be carried out in patients at risk. Allow a 12-h	Cystectomy patients are considered at risk; prolonged prophylaxis should therefore be administered	NA/high

	interval between injections and epidural manipulation.		
8. Epidural analgesia	Thoracic epidural analgesia is superior to systemic opioids in relieving pain. It should be continued for 72 h.	—	NA/high
9. **Minimally invasive approach**	At most feasible; in trial setting Long-term oncologic results awaited	Laparoscopic/robotic cystectomy is not recommended outside a trial setting until long term results are available.	Low/mo
10. Resection site drainage	Perianastomotic and/or pelvic drain can be safely omitted.	Because of urine leak, drainage might be required in cystectomy patients.	NA/low
11. Antimicrobial prophylaxis and skin preparation	Patient should receive single-dose antimicrobial prophylaxis 1 h before skin incision. Skin preparation with chlorhexidine-alcohol prevents/decreases surgical site infection.	—	NA/high
12. Standard anesthetic protocol	To attenuate the surgical stress response, intraoperative maintenance of adequate hemodynamic control, central and peripheral oxygenation, muscle relaxation, depth of anesthesia, and	—	NA/mod

	appropriate analgesia is recommended.		
13. **Perioperative fluid management**	Fluid balance should be optimized by targeting cardiac output using the esophageal Doppler system or other systems for this purpose and avoiding overhydration. Judicious use of vasopressors is recommended with arterial hypotension.	High-risk patients need close and individualized goal directed fluid management. There are several ways to achieve this and all must be used together with sound clinical judgment.	Low/hig
14. Preventing intraoperative hypothermia	Normal body temperature should be maintained preoperatively and postoperatively.	Especially relevant for cystectomy patients because operative duration is prolonged.	Na/high
15. **Nasogastric intubation**	Postoperative nasogastric intubation should not be used routinely.	Early removal is recommended.	Low/hig
16. **Urinary drainage**	Transurethral catheter can be removed on postoperative day 1 after pelvic surgery in patients with a low risk for urinary retention.	Ureteral stents and transurethral neobladder catheter should be used. The optimal duration of ureteral stenting (at least until POD 5) and transurethral catheterization is unknown.	Very low
17. **Prevention of postoperative ileus**	A multimodal approach to optimize gut function should involve gum chewing and oral magnesium.	—	Moderat
18. **Prevention of PONV**	Multimodal PONV prophylaxis should be adopted in all patients with two risk factors.	Multimodal prophylaxis	Very low risk patie
19. Postoperative	Multimodal	—	NA/high

analgesia	postoperative analgesia should include thoracic epidural analgesia.		
20. Early mobilization	Early mobilization should be encouraged.	2 h out of bed POD 0 6 h out of bed POD 1	NA/low
21. Early oral diet	Early oral nutrition should be started 4 h after surgery.	—	NA/mod
22. Audit	All patients should be audited for protocol compliance and outcomes.	Routine audit of outcomes, cost-effectiveness, compliance, and changes in protocol.	NA/low

Bolded recommendations have been directly studied in urology patients undergoing radical cystectomy.

LMWH, Low–molecular-weight heparin; *Na,* not available; *PONV,* postoperative nausea and vomiting.

Modified from Cerantola Y, Valerio M, Persson B, et al. Guidelines for perioperative care after radical cystectomy for bladder cancer: Enhanced Recovery After Surgery (ERAS®) society recommendations. *Clin Nutr* 32:879–887, 2013.

It is interesting to note that the majority of these recommendations are extrapolated from colorectal surgery literature without any direct evidence from the cystectomy population supporting their use. **Only 7 of the 22 ERAS recommendations, as outlined by the ERAS Society guidelines are backed by direct evidence from urology patients** (Cerantola et al., 2013).

With improved understanding, progress has been made in the perioperative care of colectomy patients, which has translated to improved care for patients undergoing radical cystectomy. It might be tempting to assume that ERAS protocols should be applied to all urinary diversion patients. However, **the use of an ERAS protocol should be carefully considered, especially in patients undergoing surgery for benign conditions.** As noted earlier, the majority of ERAS studies exclude patients with a history of radiotherapy, immunosuppression, or liver or renal dysfunction, making it unclear whether results from these trials are broadly generalizable. Additionally, patients undergoing urinary diversion for benign reasons often do so in the setting of a neurologic condition (such as spinal cord injury), chronic infection, radiation cystitis (with the possibility of concomitant radiation-damaged bowel), or chronic systemic syndrome such as interstitial cystitis (Chong et al., 2014). Many of these patients have decreased bowel motility, poor wound healing, impaired immunity, and other complicating factors.

It is our practice to enroll those patients undergoing radical cystectomy for bladder malignancy in our ERAS protocol (Table 139.7). In contrast, patients undergoing salvage radical cystectomy after trimodality therapy or cystectomy for benign conditions (e.g., radiation cystitis, fistula to the pubic symphysis, neurogenic bladder) are managed more conservatively, given the possible complicating factors outlined earlier. We typically subject these patients to a full mechanical and antibiotic bowel prep, and are slow in advancing their diet until bowel function returns.

Multimodal Antiemetic Regimen ☐ **Ondansetron 4 mg IV standing** ☐ Metoclopramide prn extra agent (age <75) **Bowel Regimen** ☐ **Famotidine 20 mg IV BID** or omeprazole 20 mg PO daily ☐ **Alvimopan 12 mg PO BID POD 1** until BM[a] ☐ **Chewing gum** standing POD 1 until BM ☐ **Bisacodyl PR** on POD 1 and daily until BM **Pain Management: Standing Nonopioid Analgesia** ☐ **Ketorolac 15 mg q6h** × 72 h ☐ **Acetaminophen 1 g q6h** (IV for 24 hr, then transition to PO) ☐ **Gabapentin 100 mg PO TID;** discontinue for dizziness, sedation ☐ **Discontinue TAP catheters on POD 2** if tolerating diet ☐ Transition to PO pain meds by	

POD 2 ☐ Opioid pain management in rare cases (if all else fails) ☐ **PICC line placement** POD 3 (for home IV fluids)	

[a] If available.

[b] Paraincisional fascial catheter used for infusion of bupivacaine for local pain control.

The comprehensive ERAS protocol used at our institution is outlined in Table 139.7. It incorporates many of the evidence-based practices described in this section.

Key Points

- A **mechanical** bowel prep decreases the amount of feces in the intestinal tract and therefore the absolute **bacterial count.**
- An **antibiotic** bowel prep decreases the **concentration** of bacteria per cubic centimeter of feces.
- Decisions about whether or not to administer a mechanical and/or antibiotic bowel prep should take into account the potential risks and benefits for each individual patient.
- Alvimopan is a peripherally acting μ-opioid receptor antagonist that prevents binding of opioids in the intestinal tract. It has limited ability to cross the blood-brain barrier, which allows for binding of opioids to μ-opioid receptors in the central nervous system for pain control.
- Most of the evidence for the use of ERAS protocols in urology is extrapolated from colorectal surgery, however, its use is supported in patients undergoing radical cystectomy and urinary diversion for bladder cancer.
- There are very limited data regarding the use of an ERAS protocol in patients undergoing urinary diversion for benign conditions.

Intestinal Anastomoses

Regardless of the type of anastomosis or the methods used to perform it, certain fundamental principles must be observed to minimize morbidity and mortality from intestinal surgery. **In urologic procedures in which gut is used, the most common cause of mortality and morbidity within the immediate postoperative period relates to complications involving the bowel,** either with the enteroenterostomy or with the segment interposed in the urinary tract. Therefore it cannot be overemphasized that great care must be taken and proper techniques used in handling bowel in urologic procedures. Unfortunately, the portion of the procedure that involves mobilization of the intestine and reanastomosis often follows a rather lengthy extirpative endeavor and is performed when the surgical team is not fresh. Therefore the following principles should be so firmly ingrained in the surgeon that they are performed without the need to recall each one specifically.

Surgical Principles

The first principle of proper technique for intestinal anastomoses is adequate exposure. The intestine should be mobilized sufficiently that the anastomosis may be performed without struggling for exposure. If possible, it is preferable to mobilize the intestine enough to perform the anastomosis on the anterior abdominal wall. The area of the anastomosis should be walled off from the rest of the abdominal cavity with Mikulicz pads. This is important so that any inadvertent enteric spills are not distributed throughout the abdominal cavity. The mesentery must be cleared from the bowel segments to be anastomosed for a suitable distance (usually 0.5 cm) from the intestinal clamps or staple line at the severed ends so that good serosal apposition may be achieved without interposed mesentery. Sufficient serosa must be exposed so that the seromuscular sutures or staples can be placed directly in the serosa without traversing the mesentery.

The second principle of performing a proper anastomosis is to maintain a good blood supply to the severed ends of the bowel. The blood supply may be compromised by construction of an anastomosis under tension, excessive dissection or mobilization of the bowel, excessive use of electrocautery, or tying of the sutures so tightly that the intervening tissue is strangulated. A cut margin of bowel that is pink and bleeds freely suggests that the blood supply has not been compromised; however, hemostasis must be ensured before beginning the anastomosis. The site of transection is selected at a point where the blood supply is adequate to both segments. The mesentery should be transilluminated so that the blood supply may be defined before transection of the bowel segment. In urologic surgery, the location of the transection is elective so that an area may be selected in which excellent arcades supply both sections of the transected segment. The area must be selected with an eye to how deep the mesenteric transection must be for proper segment mobility. After location of the appropriate area where the mesentery is to be transected, it is cleared from the serosa, severed between mosquito clamps, and tied with 4-0 silk sutures. Alternatively, the mesentery may be transected with the LDS stapler (Covidien Surgical, Mansfield, MA), a bipolar cautery device, or ultrasonic shears.

The third principle involves prevention of local spillage of enteric contents. The best way of preventing spills is to operate on properly prepared bowel (i.e., devoid of feces and collapsed). Stripping of the enteric contents between the fingers both cephalad and caudad from the proposed transection site and application of a noncrushing occlusive clamp across the bowel make a spill even less likely. The clamp should prevent enteric contents from exiting the cut ends of the bowel without interference with the mesenteric blood supply. After linen-shod clamps are applied and the area is walled off, Allen clamps are applied to the bowel, and the bowel is transected between the Allen clamps. An anastomotic stapler may be used to transect the bowel at this point in place of Allen clamps (see later). Local spills and local sepsis have an adverse effect on the healing anastomosis, and it is for this reason that noncrushing occlusion clamps and bowel preparation may be useful. If a spill does occur, it should be caught in the Mikulicz pads if the bowel has been properly walled off as described earlier. The isolated segment that is to be used in the reconstructive procedure should be irrigated thoroughly with copious amounts of normal saline. The segment should be walled off. The irrigant is placed in one end of the segment and caught in a kidney basin as it exits the other end. This should be continued until the efflux is clear. This procedure prevents local spills during the ureterointestinal anastomosis and other aspects of reconstruction.

The fourth principle, germane to all intestinal anastomoses, is that **there should be an accurate apposition of serosa to serosa of the two segments of bowel to be anastomosed.** The anastomosis should be watertight and performed without tension. The bowel must be handled gently with the use of noncrushing forceps. The anastomotic line should be inverted and not everted. There is considerable controversy about this issue in that an everted anastomosis has been shown to heal with few complications. It is clear, however, that when marginal conditions occur, an inverted anastomosis is more likely to remain intact than is the everted anastomosis.

The fifth principle is not to tie the sutures so tightly that the tissue is strangulated. Obviously, the sutures must bring the serosa of the two segments firmly together. Nonabsorbable sutures used for the anastomosis result in a stronger anastomotic line in the early healing phase compared with absorbable sutures, but the difference is minimal and probably not particularly significant.

The final principle involves realignment of the mesentery of the two segments of bowel to be joined. These should be parallel to each other; the surgeon should ensure that there is no twist on completion of the anastomosis. Closing the bowel mesentery is classically recommended, though it remains a matter of debate. In bariatric surgery, where this has been most thoroughly studied, some authors suggest a decrease internal hernia rate after mesenteric closure (Steele et al., 2008), and others report an extremely low internal hernia rate without closure of any mesenteric defects (Cho et al., 2006). There is little direct evidence from urinary diversion patients.

Factors that significantly contribute to anastomotic breakdown include poor blood supply, local sepsis induced by fecal spillage, drains placed on an intra-abdominal anastomosis, and anastomosis performed in irradiated bowel. Poor blood supply and local sepsis cause ischemia. Drains placed on the anastomosis increase the likelihood of an anastomotic leak, and an anastomosis performed in irradiated bowel is more likely to result in an anastomotic failure than one performed in nonirradiated tissue. The importance of careful technique and adherence to these principles is emphasized by the fact that in one series of urinary intestinal diversion, **75% of the lethal complications that occurred in the postoperative period were related to the bowel. Eighty percent of these patients had received radiation before the intestinal surgery** (Månsson et al., 1979)**. Prior radiation significantly increases the likelihood of serious complications after radical cystectomy** (Eswara et al., 2012).

Types of Anastomoses

Intestinal anastomoses may be performed with use of sutures or staples. Properly performed, both have similar complication rates (Catena et al., 2004). In selected circumstances, however, one method may have advantages over the other. **Because there is a high rate of stone formation on surgical staples** (Woodhouse and Robertson, 2004)**, absorbable suture should be used for intestinal segments that are exposed to urine,** for example, suturing intestine to renal pelvis or bladder, closing the proximal end of a conduit (Costello and Johnson, 1984), and forming an intestinal pouch for urine. With the advent of minimally invasive cystectomy, stapled neobladders have become an alternative to hand-sewn pouches. One study has reported a stone formation rate comparable to that reported in the literature for completely hand-sewn ileal reservoirs at a mean follow up of 41 months (Ferriero et al., 2015). The long-term durability of these findings is still to be determined.

Enteroenterostomy by a Two-Layer Suture Anastomosis

A 3-0 silk holding suture is placed on the mesenteric border just beneath the Allen clamps traversing both segments to be anastomosed, and a second suture is placed on the antimesenteric border similarly just beneath the Allen clamps (Fig. 139.3). It is important that the mesentery be cleared sufficiently so that these sutures can be placed in the serosa under direct vision. A row of silk sutures is placed 2 mm apart between the two holding sutures. This is accomplished by rotating the two Allen clamps away from each other, thus apposing the serosal surfaces. Sutures must traverse the muscularis but should not traverse the full thickness of the bowel. After all sutures have been placed, each is tied and the tails of all sutures are cut, except those at each end; these are used as holding sutures. The Allen clamps are removed, and hemostasis is achieved, if necessary, with the light application of electrocautery. A 3-0 double-ended chromic intestinal suture is placed in the posterior suture line through all layers and tied to itself. Each end of the suture is then run in a locking fashion away from the midpoint until the mesenteric and antimesenteric borders are approached. As the lateral aspects of the bowel are approached, the suture is converted to a Connell suture (Fig. 139.4), which proceeds onto the anterior bowel wall. The sutures meet anteriorly in the midline and are tied together. The anterior serosa is then apposed with interrupted 3-0 silk sutures. The noncrushing occlusive clamps are removed, and the mesentery is closed with interrupted 3-0 silk sutures. Patency of the anastomosis is ensured by palpating the anastomosis with the thumb and forefinger and feeling an annulus of tissue around the fingers.

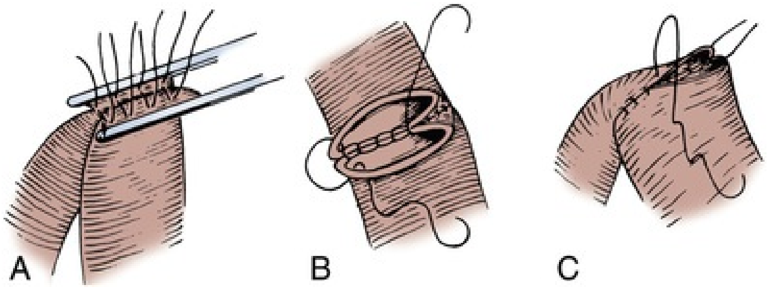

FIG. 139.3 Two-layer suture anastomosis. (A) Two holding sutures of 3-0 silk have been placed at the mesenteric and antimesenteric border, and the posterior wall is approximated with seromuscular sutures of 3-0 silk. (B) A 3-0 intestinal chromic suture is placed through the full thickness of the bowel posteriorly, tied to itself, and run to the lateral borders with a continuous locking suture. At the lateral borders, it is converted to a Connell suture. (C) The Connell suture brings the anterior margins together, inverting the suture line. The anastomosis is completed by placement of horizontal mattress seromuscular sutures of 3-0 silk over the anterior suture line (not depicted).

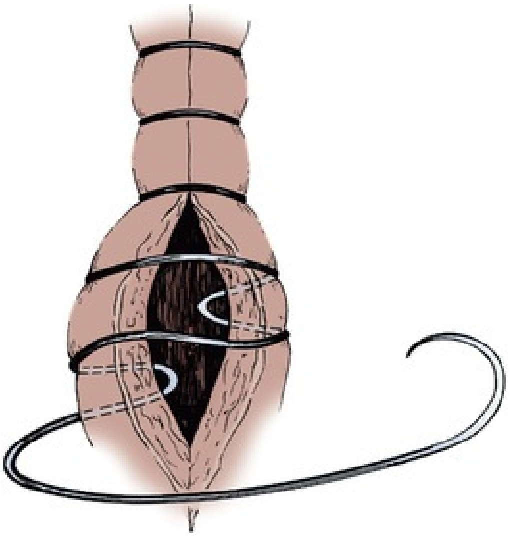

FIG. 139.4 Connell suture. The suture traverses the bowel from serosa to mucosa and then from mucosa to serosa on the same side of the anastomosis. The suture is then placed on the opposite side of the anastomosis “outside in–inside out.” The sequence is repeated until the two segments are approximated.

This anastomotic technique is used when the antrum pylorus is removed and intestinal continuity is restored by a Billroth I procedure. It is also the most secure of all the anastomoses and should be used when one is forced to do an anastomosis under less than ideal circumstances.

Enteroenterostomy by a Single-Layer Suture Anastomosis

The single-layer anastomosis for reapproximating bowel is an excellent technique with a low complication rate, that is, a 0.2% anastomotic leakage rate compared with an 8.4% anastomotic leakage rate for a stapled anastomosis in one large series (Leslie and Steele, 2003).

The mesenteries of the two segments of bowel to be anastomosed are aligned, and a 3-0 silk suture is passed through the seromuscular layers of both segments on the mesenteric side; a second suture is similarly placed on the antimesenteric side. The mesenteric suture is tied, and the antimesenteric suture is left untied. The Allen clamps are removed, and hemostasis is achieved with light electrocautery. The critical point of the anastomosis, where most leaks occur, is at the mesenteric border. Leaking usually occurs because the sutures are placed carelessly or the serosa has not been cleared of mesentery sufficiently that the sutures can be placed through it under direct vision. Because this mesenteric border is the critical area, it is approached first. Two 3-0 silk sutures are placed through the full thickness of the bowel on either side of the mesenteric holding suture. These sutures are placed in such a way as to include more serosa than mucosa, thus causing inversion of the suture line (Fig. 139.5A). Some prefer to use a Gambee stitch at this point, which involves placing the suture through the full thickness of the bowel followed by traversing a small segment of mucosa of each segment of bowel before exiting through the full thickness of the bowel of the other segment (see Fig. 139.5B). The two bowel sutures on the mesenteric border are tied, with care taken to invert the suture line, thus apposing serosa. Then 3-0 silk sutures are placed 2 mm apart, both on the anterior and posterior walls, inverting the suture line, thus apposing the serosa of the two bowel segments to each other. On approaching the antimesenteric holding suture, several sutures are placed before all are tied. A patent anastomosis is confirmed by feeling the annulus with the thumb and forefinger as described earlier.

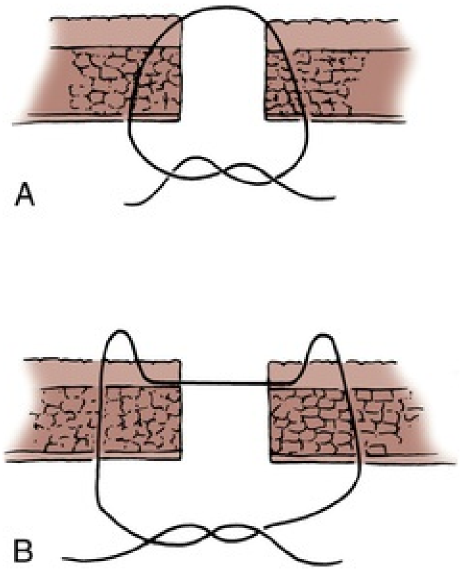

FIG. 139.5 (A) When it is properly placed, the suture through the intestine should include more serosa than mucosa. (B) The Gambee stitch. The suture is placed through the full thickness of the bowel, the mucosa is traversed, and then the mirror image procedure is performed on the segment to be anastomosed.

End-to-Side Ileocolic Sutured Anastomosis

The transected end of the colon is closed in the manner shown in Fig. 139.6. A 3-0 silk suture is placed beneath the Allen clamp on the mesenteric border, and a second suture is placed on the antimesenteric border. These are tied. A 3-0 chromic suture is placed beneath the clamp in a horizontal mattress fashion. Beginning at the mesenteric border, it is tied to itself, and the horizontal mattress suture is placed until the antimesenteric border is reached, at which point the suture is again tied to itself. The clamp is removed, and an over-and-over suture is performed with the same chromic suture through the full thickness of the bowel until returning to the point of origin (i.e., the mesenteric border is approached). At this point, the suture is again tied to itself. The suture line is buried by approximating the serosa on each side with interrupted 3-0 silk sutures placed 2 mm apart. Our preference is to close the end of the colon similarly to the way one closes the proximal end of a conduit. After a 3-0 silk suture is placed through the serosa on the antimesenteric and mesenteric sides, the clamp is removed and a 3-0 chromic suture is placed through all layers at the mesenteric and antimesenteric end. A Connell suture is used—the two chromic sutures meet in the middle and are tied together. Seromuscular sutures of 3-0 silk are placed to appose the serosal margins.

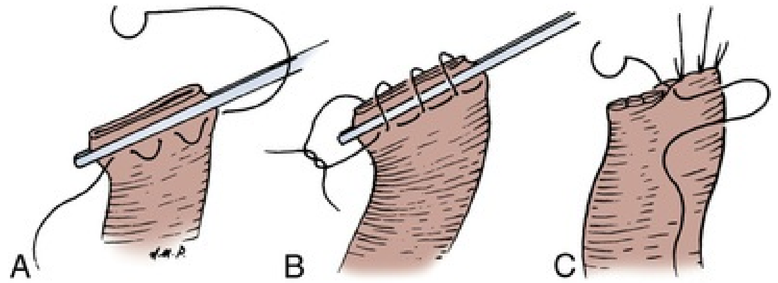

FIG. 139.6 Closure of the proximal end of the intestine. (A) A 3-0 chromic suture is tied to itself at the antimesenteric border and placed beyond the intestinal clamp in a horizontal mattress fashion until the mesenteric border is reached. The suture is then tied to itself at this point. (B) The intestinal clamp is removed, and an over-and-over suture through the full thickness of the bowel returns the chromic suture to its point of origin, where it is again tied to itself. (C) Interrupted horizontal mattress seromuscular sutures of 3-0 silk invert the chromic suture line.

The mesenteries are aligned, and the ileal serosa is sutured with interrupted 3-0 silk sutures to the colonic serosa 2 mm below a taenia (Fig. 139.7). The taenia is incised the length of the diameter of the ileum adjacent to it. As described earlier for the two-layer anastomosis, a 3-0 double-ended intestinal chromic suture is placed through all layers of the colon and ileum in the midpoint of the posterior wall and run in a locking fashion laterally to either side of the incision in the taenia. At the most lateral border, the suture is converted to a Connell suture, and the anterior wall is closed. Seromuscular sutures of 3-0 silk placed from ileum to colon bury the anterior suture line. The mesentery is then reapproximated.

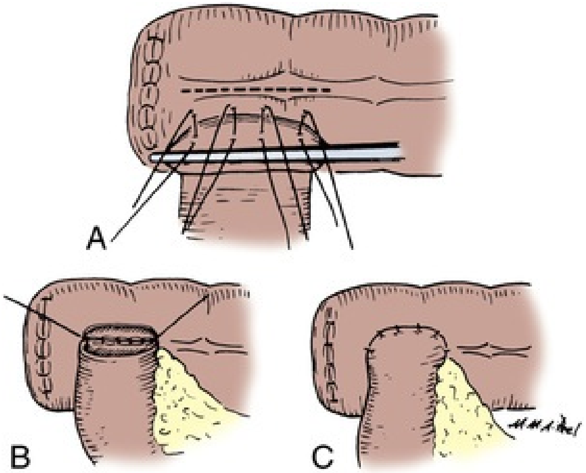

FIG. 139.7 End-to-side anastomosis. (A) The serosa of the ileum is sutured to the serosa of the colon 2 to 3 mm below a taenia. (B) The taenia

is opened for a distance sufficient to accommodate the diameter of the ileum. A 3-0 chromic suture is placed through all layers on the posterior wall, tied to itself, run in a locking fashion to both borders, and converted to a Connell suture laterally, thus completing the inversion anteriorly. (C) The anterior margin of serosa is reapproximated with interrupted horizontal mattress sutures of 3-0 silk.

Ileocolonic End-to-End Sutured Anastomosis With Discrepant Bowel Sizes

A 3-0 silk suture is placed on the mesenteric border of the ileum and colon (Fig. 139.8). A second 3-0 silk suture is placed on the antimesenteric border of the colon immediately beneath the Allen clamp. The other end of the suture is placed on the antimesenteric border of the ileum at a distance proximal to the Allen clamp so that the serosal lengths between the two sutures of both ileal and colon segment are equal. Thus an equal amount of ileal serosa is applied to the length of colonic serosa bordering the severed end of bowel. In the seromuscular layers of ileum and colon, 3-0 silk sutures are placed 2 mm apart, thus apposing the serosa of the ileum to the colon. The Allen clamps are removed. Hemostasis is achieved, and the antimesenteric border of the ileum is incised to the level of the most proximal suture in the ileum. Thus the bowel lumens are now of identical size. With a 3-0 chromic double-ended intestinal suture, the posterior row is run in a locking fashion, laterally converting to a Connell suture, and the anterior row is completed. Seromuscular sutures of 3-0 silk bury the anterior suture line.

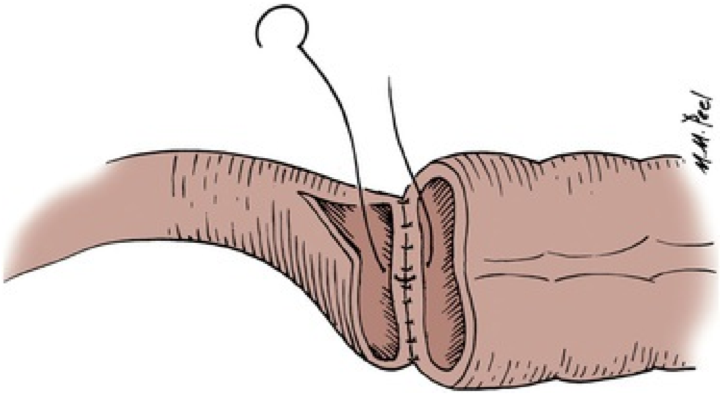

FIG. 139.8 Anastomosis of discrepant-sized bowel. A seromuscular suture of 3-0 silk is placed adjacent to each end of the lumen on the mesenteric side. A second 3-0 silk seromuscular suture is placed adjacent to the lumen on the colon and on the antimesenteric border proximal to the

cut end of the small bowel at a distance sufficient that when the antimesenteric border is incised, the lumens are the same size. Interrupted seromuscular sutures of 3-0 silk are then placed at 2-mm intervals between the two holding sutures. The small bowel is opened on its antimesenteric border until the opening in the small bowel is the same size as the opening in the colon. A 3-0 chromic suture is placed through all layers, tied to itself, and run laterally in a running locking fashion. At the borders, it is converted to a Connell suture, thus inverting the anterior margin. The anastomosis is completed with interrupted horizontal mattress 3-0 silk sutures that bring the seromuscular layers together anteriorly. This is similar to the closure depicted in Fig. 139.3.

Stapled Anastomoses

The theoretical benefits of a stapled anastomosis are that it provides for a better blood supply to the healing margin, there is reduced tissue manipulation, there is minimal edema with uniformity of suture placement, a wider lumen is constructed, there is greater ease and less time involved in performing the anastomosis, and the length of postoperative paralytic ileus is reduced. When they are placed in intestine through which urine traverses, however, stapled anastomoses using nonabsorbable staples frequently cause stone formation and should be avoided (Costello and Johnson, 1984; Woodhouse and Robertson, 2004).

The TA (transverse anastomosis) stapled anastomosis everts the suture line. Because staples close in a B configuration and do not crush the tissue, theoretically they prevent ischemia at the suture line. This may be obvious when a staple line is used to transect the bowel and bleeding continues to occur. The bleeding points may be lightly electrocoagulated or tied off with fine absorbable suture. Stapled bowel anastomoses have been shown to be as efficacious as hand-sewn anastomoses because both have similar complication rates. **They usually require less time to perform when the techniques are properly learned, but for prolonged procedures they save little if any time when the length of time for the whole procedure is taken into account.** In a large prospective, randomized trial in which a two-layer closure was compared with staple closure, it was found that the complication rate was the same, but the time required to complete the stapled anastomosis was 10 minutes less than that for the hand-sewn anastomosis; when the total operative time was compared between the two, it was the same (Didolkar et al., 1986). **A comparison of complications between sutured and stapled anastomoses reveals a leak and**

fistula rate of 2.8% for stapled and 3% for sutured anastomoses (Chassin et al., 1978). The clinically significant leak rate, however, is only 0.9% (Fazio et al., 1985). A 4.5% incidence of stapled anastomotic leakage has been reported during ileal conduit construction (Costello and Johnson, 1984).

Thus the use of staples or sutured anastomosis is at the discretion of the surgeon (MacRae and McLeod, 1998). A stapled anastomosis appears to be superior to a hand-sewn anastomosis in an esophageal-intestinal anastomosis and a low rectal anastomosis. In these two areas, the circular stapler allows a more precise anastomosis than is often possible with hand-sewing techniques. Because these are not problems of urologic surgery, staples are used if that is the preference of the surgeon. The one area in urology in which we believe the stapling device is superior is in the ileocolonic end-to-side anastomosis. With use of the circular stapling device, a widely patent anastomosis can be achieved expeditiously.

Three staple instruments are commonly used in intestinal reconstruction: the linear stapler, the anastomotic stapler, and the circular stapler. The linear stapler places a double or triple row of staggered staples in a straight line. Depending on the cartridge and instrument chosen, various lengths of staple lines and heights of the closed staples may be chosen. The length is selected according to how long one wants the staple line to be. **The height of staple is selected according to the tissue to be stapled.** Vascular and pulmonary tissues require staples with a closed height of 1 mm (open height of 2.0 to 2.5 mm). Most intestinal anastomoses are performed with medium staples, which have a closed height of approximately 1.5 mm (open height of 3.5 mm). On occasion, for thick tissues, large staples are required that have a closed height of 2 mm (open height of 4.8 mm). If there is any doubt in selecting the staple size, the tissue thickness may be measured with a special instrument used for this purpose. In general, **tissues less than 1 mm or more than 3 mm in thickness are not amenable to the use of staples.** Staplers with a variety of staple heights within the same cartridge have recently grown in popularity and should provide more safety in situations with varying tissue thicknesses.

The anastomotic stapler places two linear double rows of staggered staples. When the knife is advanced, the staple line is divided. The height of the staples is also chosen according to the tissue to be transected.

The circular stapler places two concentric, staggered circular staple rows and cuts the tissue within the circle completely from the surrounding tissue. It may be selected in various diameters and with various heights of staples. The diameter and height are selected according to the tissue to be anastomosed. The diameter to be selected is determined by sizing the diameter of the tissue to be stapled. Special sizers are available for this maneuver. In most intestinal anastomoses in urology, the height of the closed staple is 1.5 to 2 mm. The following is a description of various types of stapled anastomoses.

Ileocolonic Anastomosis with the Circular Stapling Device

The mesenteric borders are cleared for a distance of 1.5 cm from the cut end of both the colon and the ileum (Fig. 139.9). Holding sutures of 3-0 silk are placed on the mesenteric and antimesenteric border of the colon. Two other holding sutures are placed on the medial and lateral walls of the colon, midway between the mesenteric and antimesenteric sutures. A purse-string suture of 2-0 polypropylene (Prolene) is placed around the ileum no more than 2 mm from the cut end. It is important to take small bites of mucosa to avoid bunching of tissue. Sutures must be placed evenly to avoid a gap. A purse-string instrument can be used for this step, if preferred. The ileal diameter is determined with sizers so that the correct circular stapler diameter instrument may be chosen—usually 25 mm. A purse-string suture is also placed in a circle, 1 cm in diameter, through which a taenia traverses on the medial aspect of the colon. A stab wound is made in the center of the colonic purse-string suture. The distal anvil of the circular stapler is removed, and the instrument is placed through the open end of the colon with its post passed out the stab wound made in the center of the purse-string on the medial wall of the colon. The purse-string is tied tight. The top anvil is then secured to the post, and the ileum is placed over it. The ileal purse-string is tied.

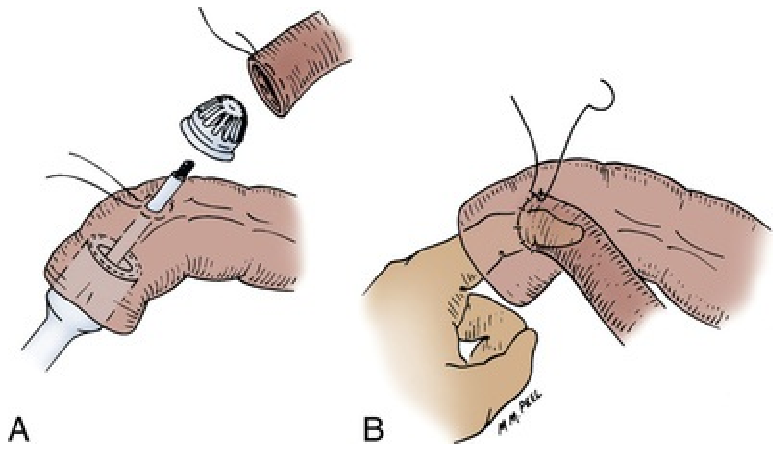

FIG. 139.9 Stapled circular anastomosis. (A) A purse-string suture of 2-0 polypropylene (Prolene) is placed around the circumference of the small bowel, and a second purse-string suture 1 cm in diameter is placed on a medial taenia 5 to 6 cm from the open end of the colon. The anvil is removed. A stab wound is made in the center of the purse-string suture in the colon, and the circular stapler is introduced through the end of the colon, with its post thrust through the stab wound. (B) The anvil is placed on the post and introduced into the end of the small bowel, the purse-string sutures in the small bowel and colon are tied snugly around the post, and the circular stapler is approximated with a gap of 1.5 to 2 mm, with care taken not to include any mesentery in the gap. The anastomosis is completed by placement of interrupted silk sutures around the circumference of the anastomosis.

Care must be taken to align the mesenteries at this point. The instrument is approximated with a staple gap of 1.5 to 2 mm. Care must be taken not to catch fat or mesentery in the gap. The instrument is fired and removed by rotatory movement from the colon. Two doughnuts of tissue should be identified on the instrument, and they should have their complete circumference intact with no gaps. With a finger in the open end of the colon and through the anastomosis, seromuscular sutures of 3-0 silk are placed 3 to 4 mm apart around the circumference of the anastomotic line.

The transected end of the colon may be closed by the suture technique or by the use of staples. If the end is to be closed with sutures, one 3-0 chromic suture is brought out the mesenteric border and another out the antimesenteric border, and both are tied to themselves with the knots on the inside of the bowel. The two sutures are run toward each other with a Connell stitch until they meet, and then they are tied to each other. The suture line is inverted by placement of a second row of 3-0 silk seromuscular sutures. If staples are preferred, the holding sutures are held up and a linear stapler is applied across the open end. Excess tissue is trimmed and the stapler removed. By holding the holding sutures up, one is secure in applying the staple line to the serosa and mucosa circumferentially around the bowel. Some invert the staple line with seromuscular sutures of 3-0 silk. This is not necessary, however. The mesentery between the two segments is now approximated with interrupted 3-0 silk sutures.

Side-to-Side Stapled Anastomosis: Ileal-Ileal or Ileocolonic Anastomosis

The antimesenteric border of the two bowel segments to be joined is approximated with a 3-0 silk suture 5 to 6 cm from the cut ends of the bowel

(Fig. 139.10). A holding suture is placed through both segments of bowel at their cut ends at the midpoint of the antimesenteric borders. Stay sutures are placed at the mesenteric border of each bowel segment, and two other sutures midway between the mesenteric and antimesenteric border on the lateral aspects of the bowel are also placed. The anastomotic stapler is positioned in the lumens of both segments of bowel along the antimesenteric border. The antimesenteric holding suture is pulled up adjacent to the stapler. The anastomotic stapler is locked in place, the staples are fired, and the knife is advanced. The staple lines are inspected for bleeders, which if persistent should be suture-ligated with an absorbable suture. It is important for several 3-0 silk sutures to be placed at the apex of the stapled and cut antimesenteric incision. At this point, slight tension on the anastomotic line can place undue stress on the staple margin and cause a leak. The holding sutures are held up, and a linear stapler is placed across the open end of bowel and fired. Care must be taken so that the staples include the serosa in its entire circumference. Excess bowel tissue is excised flush with the instrument before it is disengaged. The mesentery is then reapproximated. **Because of its simplicity and reliability, this is the most common type of anastomosis used in urology.**

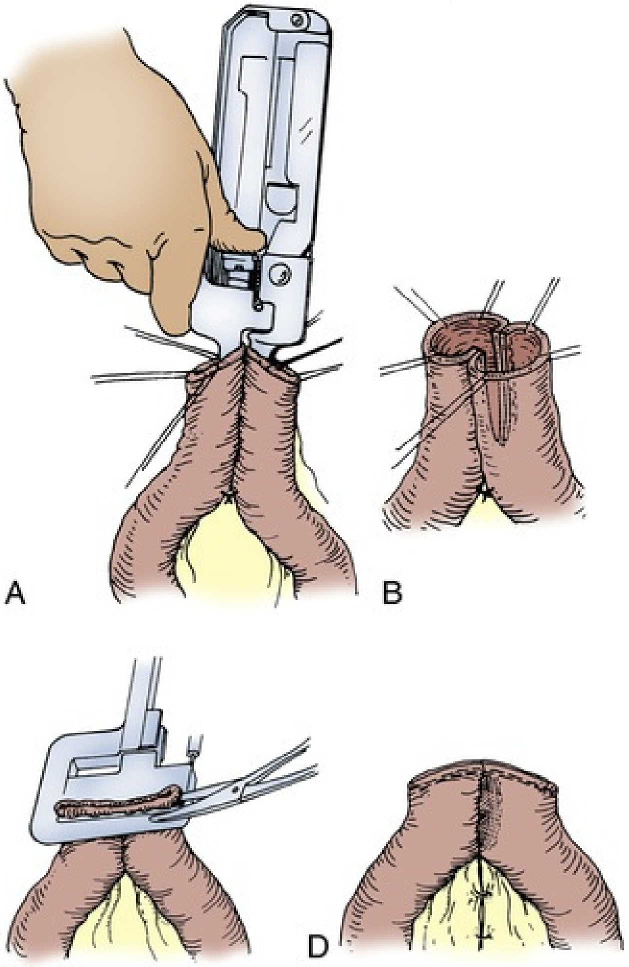

FIG. 139.10 Stapled side-to-side anastomosis. (A) A 3-0 silk suture is placed 5 to 6 cm from the cut ends of the intestine on the antimesenteric borders of both intestinal segments and tied. Holding sutures are placed around the circumference of both intestinal lumens, one suture securing together the antimesenteric borders of both intestinal segments. The linear anastomotic stapler is placed into the lumens, secured and locked in place, and fired. The knife is advanced. (B) The appearance of the intestinal anastomosis after firing of the stapler. (C) The open end of the two intestinal segments is closed with a linear stapler by elevation of the holding sutures while the linear stapler is applied so that the circumferences of the mucosa and serosa are incorporated in the staple margin. (D) The anastomosis is completed by closure of the mesentery with interrupted 3-0 silk sutures.

Laparoscopic and Robotic Anastomoses

Laparoscopic and robotic approaches to cystectomy with urinary diversion and to augmentation cystoplasty are becoming more commonly accepted (Goh et al., 2012; Guillotreau et al., 2009). In these procedures of urinary diversion, a purely laparoscopic or robotic technique is possible for bowel resection with the use of endoscopic stapling devices. Proper placement of the trocars is dependent on the need to mobilize the bowel and the procedure for which the bowel is to be used. Trocar placement for mobilization of the distal ileum is illustrated in Fig. 139.11. The technique primarily involves the use of endoscopic linear cutting and stapling devices, which can be used to divide small bowel and its mesentery (Figs. 139.12 and 139.13). Reanastomosis purely intracorporeally can be accomplished with the same endo-GIA stapler to reconstitute bowel continuity with a side-to-side anastomosis (Gill et al., 2000; Potter et al., 2000). An endoscopic TA stapler may be used to complete the bowel closure.

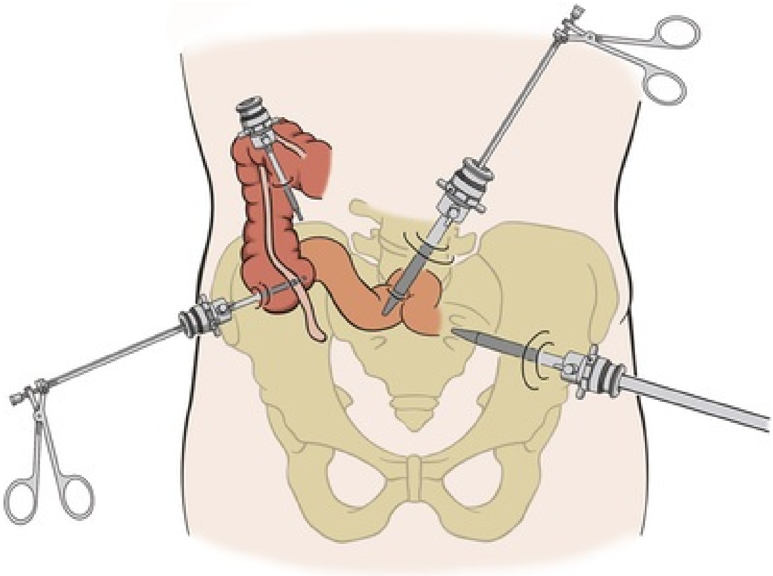

FIG. 139.11 Trocar placement for laparoscopic mobilization of the distal ileum.

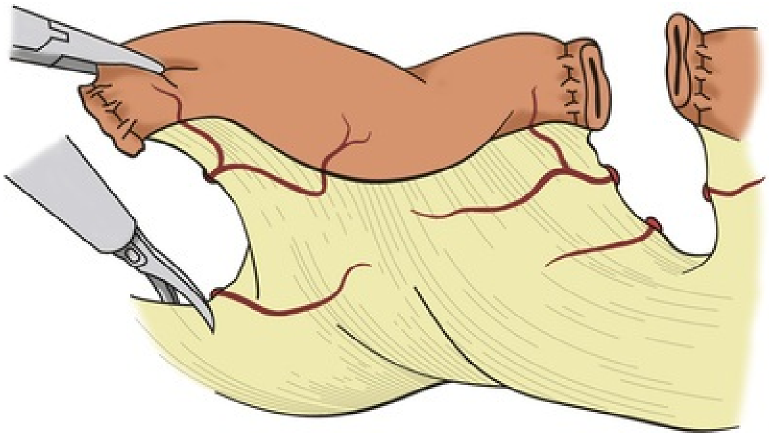

FIG. 139.12 Laparoscopic mobilization of a small bowel segment for use in reconstruction. The visceral peritoneum is divided sharply; then the mesenteric vessels are ligated and divided. Staplers, ultrasonic shears, or bipolar cautery devices may be used to divide the mesenteric vessels.

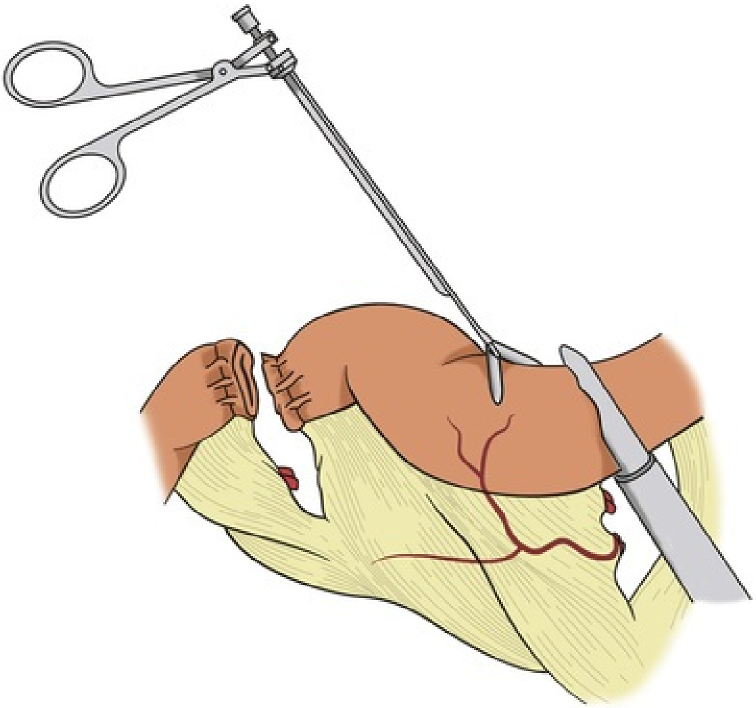

FIG. 139.13 The endoscopic gastrointestinal stapler divides the intestinal segment. The staple line must be excised from the segment intended for use in the urinary reconstruction.

A laparoscopic or robotic ileal conduit can be performed with these techniques as well. In a laparoscopic approach, the ureterointestinal anastomosis is performed with freehand laparoscopic suturing. One of the abdominal trocar sites is used to draw the bowel segment through the abdominal wall for stoma construction.

A completely intracorporeal laparoscopic orthotopic ileal neobladder has been described (Gill et al., 2002). The neobladder is constructed by freehand running suture with use of laparoscopic techniques (Fig. 139.14). The results of laparoscopic bowel anastomoses suggest that these anastomoses are safe (Canin-Endres et al., 1999; Rothenberg, 2002), but no large series that compares open with laparoscopic approaches for bowel anastomosis has been published.

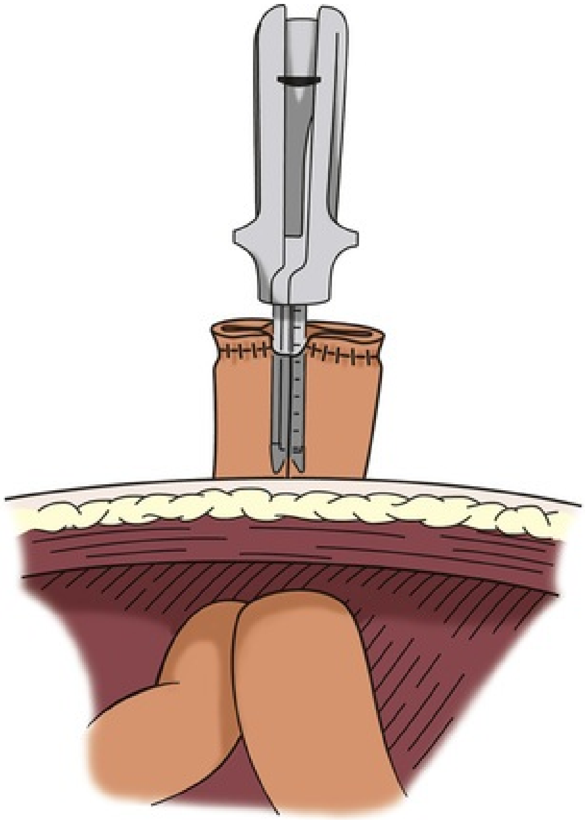

FIG. 139.14 Many urologic procedures in which intestinal segments are used for reconstruction involve extirpative surgery in which a small laparotomy is used for specimen removal. In this case, the small laparotomy is used to deliver the bowel segment outside the abdomen. Any form of anastomosis may be used by this technique, which also reduces the chance of spillage of intestinal contents.

Completely robotic surgical approaches to radical cystectomy with orthotopic neobladder have become increasingly common. A barbed monofilament suture may facilitate suturing of the neobladder (Tyritzis et al., 2012). Approaches using only nonabsorbable staples have also been described (Abreu et al., 2005).

Although intracorporeal neobladder reconstruction is in its infancy, initial perioperative results appear to be comparable to open surgery in well-selected patients (Fahmy et al., 2015).

Other approaches to laparoscopic or robotic intestinal surgery include laparoscopic mobilization of the bowel segment and exteriorization of the segment; the anastomosis of the bowel and ureteral anastomoses are then performed in an open fashion through a small laparotomy incision (Fig. 139.15). This is now the preferred approach for many performing laparoscopic or robotic cystoprostatectomy. **Purely laparoscopic intestinal anastomoses in radical cystectomy are associated with a higher complication rate from intestinal and ureteral anastomotic leaks than an exteriorized approach** (Stephenson and Gill, 2008). In radical cystectomy, a small incision is already required for intact specimen removal. An open approach therefore allows direct tactile assessment of the anastomoses.

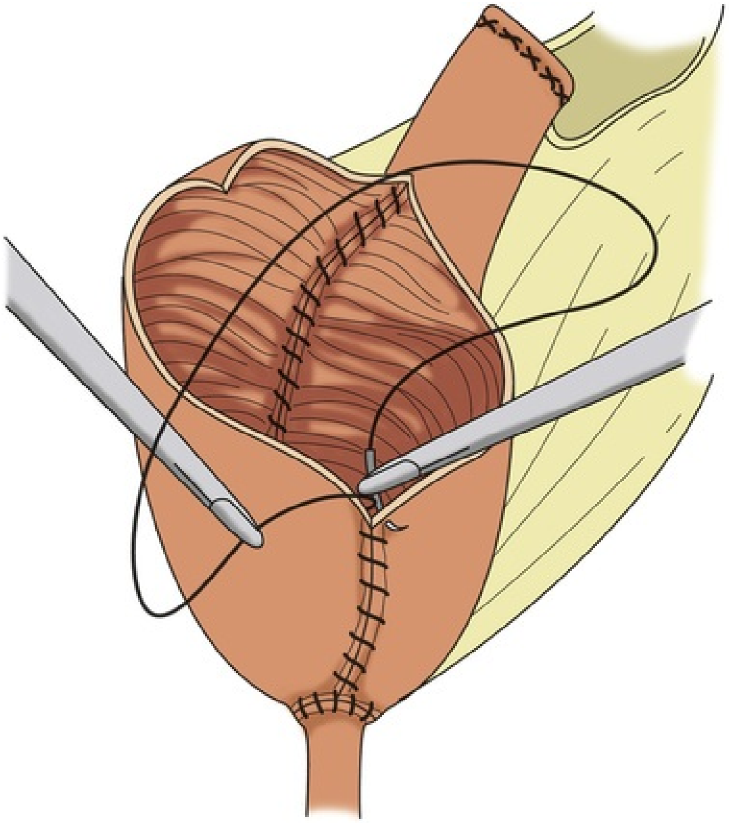

FIG. 139.15 Completely intracorporeal laparoscopic construction of a small intestinal neobladder; 2-0 polyglycolic acid suture is used in a running closure of the pouch.

Compression Anastomoses and the Biofragmentable Ring

There is a long history of experimental work on compression anastomoses. These technologies may facilitate natural orifice and minimally invasive surgery. With the most clinical evidence, the biofragmentable ring has proven safe, effective, and time-efficient. Several studies have shown that these intestinal anastomoses are as safe as hand-sewn or stapled anastomoses (Ghitulescu et al., 2003). Other compression devices have been devised but have not gained in popularity (Kaidar-Person et al., 2008).

Complications of Intestinal Anastomoses

The complications that follow anastomoses include leakage of fecal contents, sepsis, wound infections, abdominal abscesses, hemorrhage, anastomotic stenosis, pseudo-obstruction of the colon (Ogilvie syndrome), and intestinal obstruction. These untoward events increase morbidity and are frequently major contributors to mortality (Hautmann et al., 2010). The complication rates for elective colocolonic and ileocolonic anastomoses performed in prepared bowel with contemporary technique are intestinal leak, 2%; hemorrhage, 1%; and stenosis or obstruction, 4%. These complications require reoperations in 1% of patients and result in death in 0.2% of patients (Jex et al., 1987). The mean time to diagnose an anastomotic leak is 12 days postoperatively; some have occurred even after 30 days (Hyman et al., 2007). Many of the complications of radical cystectomy are attributable to the use of intestinal segments for urinary diversion (Takada et al., 2012).

Fistulas

Fistulas in the postoperative period are of two types: fecal and urinary. **These generally occur within the first several weeks after the operative event.** They frequently result in sepsis and markedly increase morbidity and mortality. Fecal fistulas occur in 4% to 5% of patients (Beckley et al., 1982; Sullivan et al., 1980). **Sepsis is a common complication of these untoward events and carries with it a mortality of 2%** (1 of 47 patients) (Hill and Ransley, 1983). In women undergoing orthotopic neobladder reconstruction after radical cystectomy, the risk for neobladder-vaginal fistula is approximately 11% and usually presents several continuous incontinence episodes several months after surgery (Rapp et al., 2004).

Sepsis and Other Infectious Complications

Wound infections, pelvic abscesses, and wound dehiscences may complicate the immediate postoperative period. Although wound dehiscences and pelvic abscesses are rare complications, wound complications occur with an incidence of 10% (Gilbert et al., 2013). Many of these complications may be averted by walling off the intestine with Mikulicz pads while the anastomosis is being completed; irrigating the intestinal segment to be used in the reconstruction until it is free of any residual enteric contents; being careful to avoid fecal spillage; and washing out the abdominal cavity and incision to dilute any contaminants. The overall septicemia rate after radical cystectomy is currently 3.6%, with a 17% mortality rate (Davies et al., 2009). When assessed for cumulative incidence of infectious complications, nearly 45% of patients after urinary diversion will require treatment (Gilbert et al., 2013).

Bowel Obstruction

The incidence of intestinal obstruction after abdominal procedures for urinary intestinal diversion differs according to whether the stomach, ileum, or colon is used for the diversion. In patients who have had a **segment of stomach or ileum removed for the diversion, there is a 10% incidence of postoperative bowel obstruction requiring treatment.** When the colon is used, the incidence of postoperative obstruction requiring an operation is 5% (Table 139.8). One-half of the bowel obstructions occur in the early postoperative period. In one series, after radical cystectomy and ileal conduit, 15% of the patients had a mild obstruction in the first 6 months that responded to conservative management, whereas 3% required an operation to relieve the obstruction during this period. The occurrence of obstruction after this 6-month period was much less frequent (Sullivan et al., 1980). More recently, a 10.5% incidence of reoperation for bowel obstruction was noted in a large series of radical cystectomy patients (Varkarakis et al., 2007). **Bowel obstruction can be a morbid event; a significant number of patients who develop obstruction after an ileal conduit and require an operation die. The most common cause of the obstruction is adhesions, followed by recurrent cancer.** These two causes account for the great majority of the cases. Volvulus and internal hernia are much more rare, but can occur (Jaffe et al., 1968). Occasionally, severe stenosis or obstruction at the anastomotic suture line can occur. Stenosis is a result of edema, poor technique, or performing the anastomosis on ischemic bowel (Fig. 139.16); obstruction is usually a result of improper technique.

TABLE 139.8

Complications of Urinary Intestinal Diversion[a]

COMPLICATION	TYPE OF DIVERSION	NO. OF PATIENTS (COMPLICATION/TOTAL NO.)	INCIDENCE (%)
Bowel obstruction	Ileal conduit	124/1289	10
	Colon conduit	9/230	4
	Gastric conduit	2/21	10
	Continent diversion	2/250	0.8
Ureteral-intestinal obstruction	Ileal conduit	90/1142	8
	Antireflux colon conduit	25/122	20
	Colon conduit	8/92	9
	Continent diversion	16/461	4
Urine leak	Ileal conduit	23/886	3
	Colon conduit	6/130	5
	Continent diversion		
	Ileum	104/629	17
	Colon	5/123	4
Stomal stenosis, hernia	Ileal conduit	196/806	24
	Colon conduit	45/227	20
	Continent diversion	28/310	9
Renal calculi	Ileal conduit	70/964	7
	Antireflux colon conduit	5/94	5
Pouch calculi	Continent diversion	42/317	13
Acidosis requiring treatment	Ileal conduit	46/296	16
	Antireflux colon conduit	5/94	5
	Gastric conduit	0/21	0

	Continent diversion		
	Ileum	21/263	8
	Colon/colon-ileum	17/63	27
Pyelonephritis	Ileal conduit	132/1142	12
	Antireflux colon conduit	13/96	13
	Continent diversion	15/296	5
Renal deterioration	Ileal conduit	146/808	18
	Antireflux colon conduit	15/103	15

[a] Composite from the literature. Follow-up averages 5 years for ileal conduits, 3 years for colon conduits, 2 years for gastric conduits, and 2 years for continent diversions.

Data is from the following sources, which can be found in this chapter's reference list:

Jaffe et al., 1968; Castro and Ram, 1970; Malek et al., 1971; Smith, 1972; Schmidt et al., 1973; Richie, 1974; Flanigan et al., 1975; Schwarz and Jeffs, 1975; Shapiro et al., 1975; Middleton and Hendren, 1976; Althausen et al., 1978; Elder et al., 1979; Hagen-Cook and Althausen, 1979; Pitts and Muecke, 1979; Sullivan et al., 1980; Beckley et al., 1982; Loening et al., 1982; Adams et al., 1988; Boyd et al., 1989; Madersbacher et al., 2003; Studer et al., 2006; Nieuwenhuijzen et al., 2008.

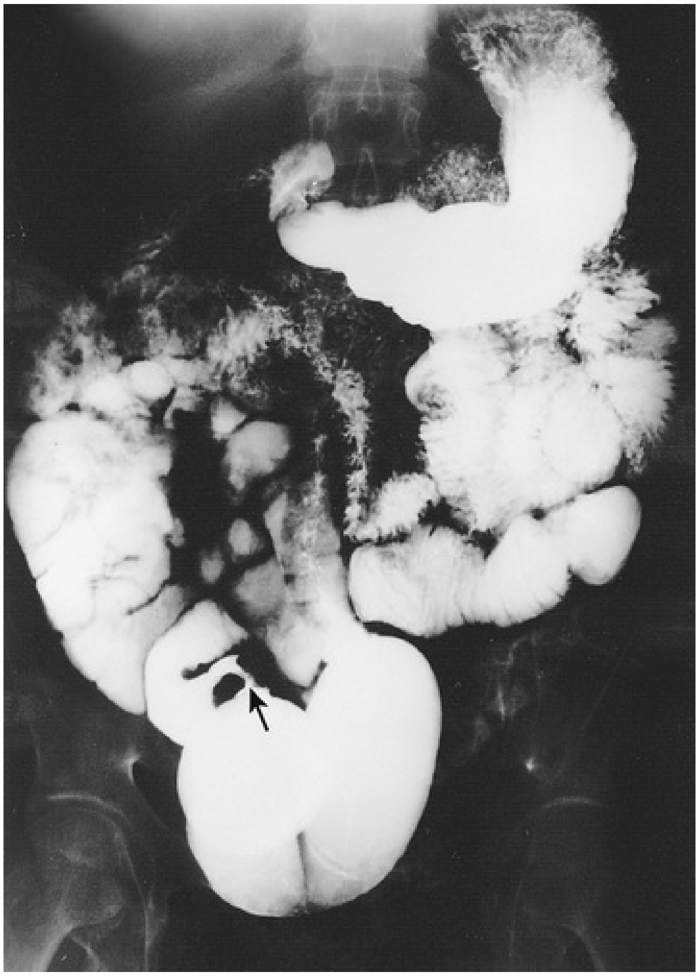

FIG. 139.16 Upper gastrointestinal tract series illustrates a small bowel stricture *(arrow)* at the ileoileostomy after ileal conduit urinary diversion. At the time of the initial ileoileostomy, the anastomotic suture line appeared bluish. At subsequent exploration, a bowel lumen of only 2 mm was found. The serosa at the anastomotic site was fibrotic.

The incidence of postoperative bowel obstruction may be reduced by using nonirradiated bowel, performing the anastomosis on well-vascularized bowel, closing all apertures, reperitonealizing the isolated segment, decompressing the gastrointestinal tract for an adequate time, placing omentum over the anastomosis, and reconstituting the pelvic floor after exenterative surgery. Orthotopic neobladders appear to result in fewer bowel obstructions than ileal conduits or cutaneous reservoirs (Hemelrijck et al., 2013). The isolated segment is reperitonealized by tacking its antimesenteric border to the lateral abdominal sidewall peritoneum. The proximal mesenteric border should be tacked to the posterior parietal peritoneum because failure to obliterate this potential space has resulted in entrapment of bowel, causing bowel obstruction. Placing the sigmoid colon in the area may close the pelvic space left after an anterior exenteration. This effectively prevents small bowel from herniating into the raw pelvis. Omentum may also be mobilized and used to fill any space the sigmoid colon does not fill. In a total exenteration, sufficient sigmoid colon is not available, and the omentum is often not bulky enough to fill the pelvis and thus prevent small bowel from filling the denuded pelvis. This situation is of particular concern in patients who must receive postoperative pelvic irradiation. The bowel may be kept out of the pelvis in these patients by reconstructing the pelvic floor with polyglactin mesh. The mesh is sutured along the posterior pelvic brim to the sacral promontory and presacral fascia and laterally to the adventitia of the iliac vessels. Laterally and anteriorly, it is sewn to the peritoneum two-thirds of the distance between the pubis and umbilicus. The omentum is then brought down, placed over the mesh, and sutured in position. This effectively excludes the bowel from the pelvis for 4 to 6 weeks while postoperative irradiation is being administered (Sener et al., 1989).

Hemorrhage

Hemorrhage is a rare complication of intestinal anastomoses. It is much more likely to occur when stomach is used and a Billroth I anastomosis is constructed. **It is usually caused by failure to secure bleeding at the time of anastomosis or by anastomotic ulcers that develop on the suture line.**

Intestinal Stenosis

Intestinal stenosis occurs at two distinct times: in the immediate postoperative period and during the long term. Intestinal stenosis in the immediate postoperative period is caused by technical mishaps or edema. Edema resolves by continuing the intestinal decompression, whereas technical mishap requires a reoperation. During the long term, it is likely caused by ischemia or perienteric infection. Fig. 139.16 shows an upper gastrointestinal tract series of a severe intestinal stenosis caused by ischemia. At the time of the ileoileostomy, the suture line was blue. Chronic symptoms of partial small bowel obstruction occurred in the postoperative period.

Pseudo-Obstruction

Pseudo-obstruction of the colon, or Ogilvie syndrome, on rare occasion may complicate the early postoperative period. Its cause is not understood. **Pseudo-**

obstruction usually occurs within the first 3 days postoperatively in patients with multiple medical illnesses. The patient develops severe abdominal pain, and a radiograph of the abdomen reveals a dilated cecum. A gentle water-soluble contrast enema eliminates the possibility of a mechanical obstruction. The presence of a rising leukocyte count or a cecum that is increasing in size and exceeds 12 cm in diameter is associated with a 23% risk for rupture (Jain and Vargas, 2012). **Pseudo-obstruction may be treated with neostigmine or endoscopic decompression. Surgical intervention rarely is necessary and should be reserved for patients with ischemia, peritonitis, or refractory cases** (Jain and Vargas, 2012).

Complications of the Isolated Intestinal Segment

Intestinal Stricture

Strictures of intestinal segments are usually late complications primarily occurring in conduits, although they have been described in ileal ureters as well. **The stricture is thought to be a consequence of lymphoid depletion of the intestine exposed to urine.** The lymphoid depletion contributes to persistent infection, which may result in midloop stricture, bacterial seeding of the upper tracts, and renal deterioration (Tapper and Folkman, 1976). Because of the persistent infection and lack of intestinal resistance to the detrimental action of bacteria, submucosal edema with fibrosis and stricture formation occurs. The intestinal segment may also be blocked by encroachment of hypertrophied mesenteric lymph nodes. **Hypertrophied mesenteric lymph nodes, submucosal lymphoid depletion, edema, and fibrosis are commonly found when intestinal segments that have been chronically exposed to urine are examined pathologically.**

Elongation of the Segment

Another complication of the intestinal segment is elongation, occasionally resulting in massive enlargement. When this occurs in conduits or ureteral substitutes, there is usually a distal obstruction. In continent diversions, it may signal failure to catheterize the pouch frequently enough. If allowed to persist, the increased pressure may result in deterioration of renal function. Enlargement and elongation of the intestine may also result in a volvulus of the segment (Fig. 139.17).

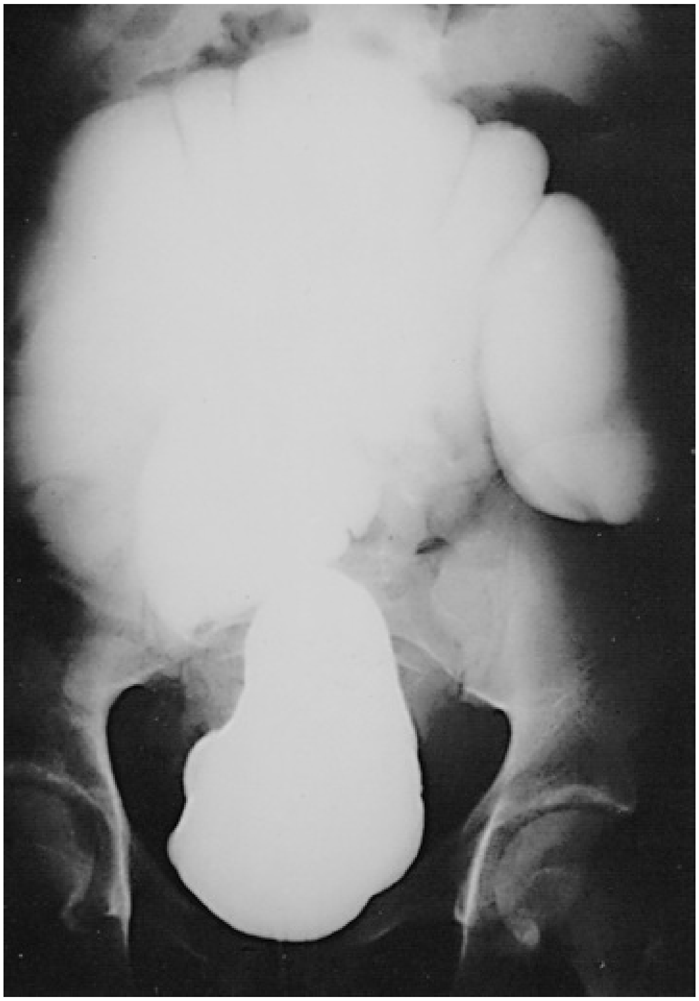

FIG. 139.17 Volvulus of an orthotopic right colon bladder. This segment enlarged markedly because of the patient's lack of adherence to a regimen of frequent intermittent catheterization.

Abdominal Stomas

Two types of stomas may be made on the anterior abdominal wall: those that are flush with the skin and those that protrude. The flush stoma is preferable for the continent type of diversion in which intermittent catheterization is carried out and over which a small dressing is placed. The stoma that protrudes is preferable when a collection device is worn. **A properly protruding stoma worn with an appliance results in a lesser incidence of stomal stenosis and a better appliance fit with fewer peristomal skin problems. There are two types of protruding stomas: the end stoma and the loop end ileostomy. Most complications of stomas are the result of technical errors in their**

construction. Therefore to minimize such complications, specific technical points must be rigidly followed.

The site of the stoma should be selected preoperatively. This is done by marking the stomal site with the patient in the sitting position and in the supine position; care is taken to place it over the rectus muscle at least 5 cm away from the planned incision line. The point chosen should be well away from skin creases, scars, the umbilicus, belt lines, and bone prominences. A site in which radiotherapy has previously injured the area should be avoided. **All stomas should be placed through the belly of the rectus muscle and be located at the peak of the infraumbilical fat roll.** If the stoma is placed lateral to the rectus sheath, a parastomal hernia is likely to occur. The bowel should traverse the abdominal wall perpendicular to the peritoneal lining (i.e., it should come straight out). One should avoid trimming fat or epiploic appendages from around the margin of the stoma, and the appliances should be applied in the operating room.

The stoma should be brought through a circular incision made at the predetermined site. A perfectly circular opening in the skin may be made by placing the finger hole of a Kelly clamp at the desired point and grasping the skin in the center of the hole with a Kocher clamp. Pulling up on the Kocher clamp and pushing the handle of the Kelly clamp against the abdominal wall allows for a small button of skin to be removed with a single pass of the knife. This makes a perfectly circular opening in the skin. However, the tendency to remove too much skin is great, resulting in a circular opening that is too large. To avoid this complication, one should not cut the skin flush with the Kelly clamp but rather immediately beneath the Kocher clamp. The subcutaneous tissue is left intact. This can be spread and does not need to be excised as any fat will fall back adjacent to the bowel and eliminate the dead space. Kocher clamps are placed on the fascia in the incision and pulled medially so that when the fascia and peritoneum are incised, they are incised directly over the skin line and thus do not result in angulation of the gut when the abdominal incision is closed. The fascia is incised in a cruciate manner, and the rectus muscles are spread. The peritoneum is incised. The opening should accommodate two fingers snugly.

Nipple (Rosebud) Stoma

A Babcock clamp is placed through the opening, and the bowel is grasped and brought out for a distance of 5 to 6 cm to make a nipple of about 2 to 3 cm in length (Fig. 139.18). Two 3-0 chromic sutures are placed through the seromuscular layer of the bowel and the peritoneum on the anterior abdominal wall. Alternatively, the serosa may be sutured to the fascia with two 2-0 chromic sutures. The mesentery is aligned in its normal anatomic direction before the serosa is sutured to the peritoneal wall. The ileum is usually curved in a concave manner toward the mesentery. If the curvature is severe, the mesentery may be partially incised 1 cm from the bowel wall (Fig. 139.19). Thus a portion of mesentery is preserved along the entire length of the bowel. This should straighten the curve in the bowel significantly if not completely. Four 3-0 chromic sutures are placed in quadrants through the full thickness of the bowel edge and through the seromuscular layer of the bowel 3 to 4 cm from the cut edge and then through the subcuticular skin layer. Sutures should not traverse the full thickness of the skin but should be placed through the subcuticular and subdermal layers only.

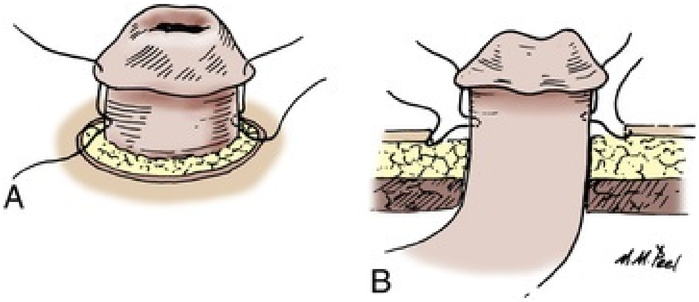

FIG. 139.18 (A and B) Nipple stoma. Five to 6 cm of intestine are brought through the abdominal wall. The serosa is scarified, and quadrant 3-0 chromic sutures are placed through the full thickness of the distal end of the intestine. Each suture is placed in the seromuscular layer 3 cm proximal and then secured to the dermis before it is tied.

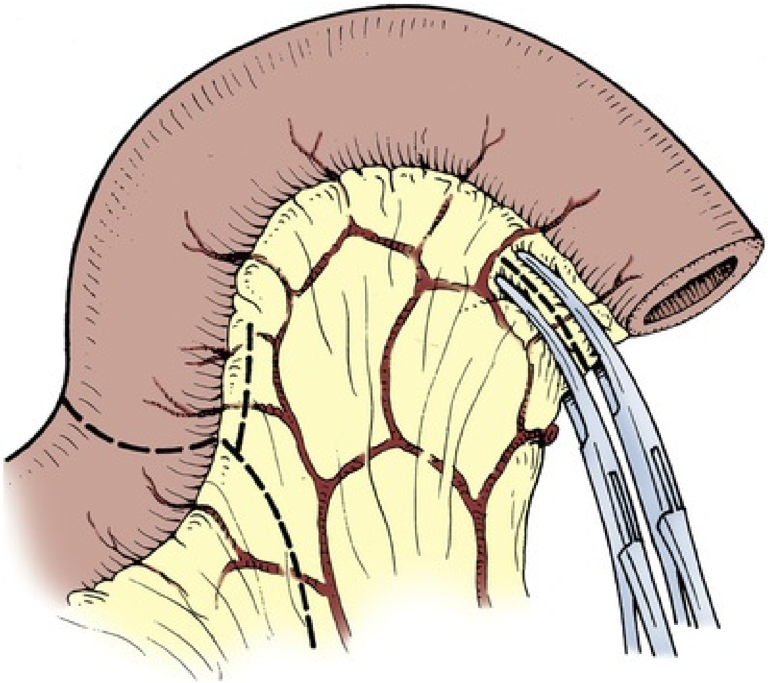

FIG. 139.19 If it is tethered by the mesentery, the bowel may be straightened by incising the mesentery several centimeters away from the serosa and parallel to the bowel.

When the sutures are tied, the bowel is everted and forms a nipple. A more secure nipple may be made by performing multiple myotomies through the seromuscular layer of the bowel above the skin line before construction of the nipple. The myotomies adhere serosa to serosa and reduce the risk for stomal retraction. This is particularly appropriate for patients who are obese.

Flush Stoma

To create a flush stoma, 3-0 chromic sutures are first placed in each quadrant. These should incorporate the full thickness of the bowel and the subdermal layer of skin. Several sutures are placed between the quadrant sutures from bowel to subdermal skin. This constructs a flush stoma that has a 1-mm raised margin.

Loop End Ileostomy

Obese patients have a thick abdominal wall and often a thick, short ileal mesentery. This makes construction of an end ileal stoma extremely difficult. **The loop end ileostomy obviates some of these problems and is usually easier to perform than the ileal end stoma in the patient who is obese** (Fig. 139.20). To construct this type of stoma, the distal end of the ileum is closed as described earlier for closing the proximal end of an intestinal segment, and a loop is brought up through the belly of the rectus muscle and onto the anterior abdominal wall. This avoids bringing the mesenteric border onto the abdominal wall and prevents one side of the ileostomy from being involved with mesentery. A slightly larger skin opening is required than for the end stoma. A 3-cm disk of skin is removed. The subcutaneous tissue is spread, the fascia incised, the rectus spread, and the peritoneum incised as described earlier. The opening should admit two fingers comfortably. The loop may be pulled through the opening in the abdominal wall by passing umbilical tape through a small opening in the mesentery at a distance from the distal end that is sufficient to leave that end in the abdomen when the loop has been pulled through the abdominal wall. By gentle traction on the umbilical tape, the loop is brought onto the abdomen.

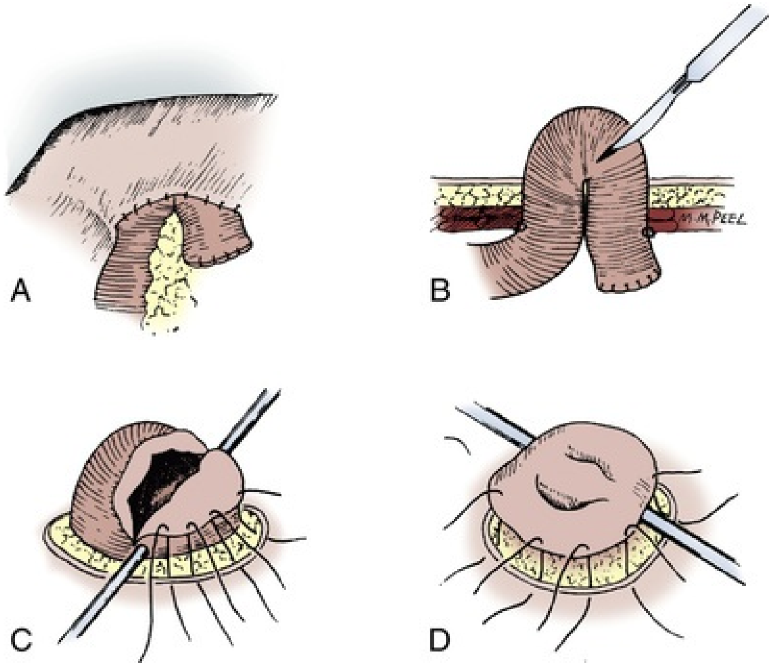

FIG. 139.20 Loop end ileostomy. (A) After the distal end of the loop is closed and the bowel is drawn through the rent in the abdominal wall, the bowel is held in place by a rod passed through the mesentery. The mesentery is realigned, and the peritoneum is sutured to the serosa of the bowel circumferentially. (B) A transverse incision is made in the bowel four-fifths of the loop distance cephalad. (C) The cephalad portion of the stoma is simply sutured to the dermal layer of skin with interrupted 3-0 chromic sutures. (D) On the inferior aspect of the incision, 3-0 chromic sutures are placed through the full thickness of the cut edge, then through the seromuscular layer, and then through the dermis. This everts the caudal portion of the stoma.

The distal portion of the bowel is brought through the opening such that the closed end lies cephalad to the body of the segment. When a sufficient amount of loop protrudes beyond the skin edge, a small rod is placed through the hole in the mesentery at the apex of the loop and holds the bowel on the anterior abdominal wall during suturing. If the rent in the rectus muscle is too large, it may be closed with interrupted 0 chromic sutures from within the abdomen. The serosa is sutured to the peritoneum on the anterior abdominal wall. The bowel wall is opened in a transverse direction at a point four-fifths of the distance cephalad to the most caudal portion of the loop. With 3-0 chromic sutures, the full thickness of the caudal incision in the bowel is sutured back to itself (serosa) and then to the dermis as in the rosebud technique. The cephalad nonfunctional opening is sutured directly to the dermis. The rod is sutured to the skin and left in place for 7 days.

The Turnbull loop stoma results in a lesser incidence of stomal stenosis but a higher incidence of parastomal hernias (Emmott et al., 1985). Overall, the two types of stoma are functionally equivalent over time (Chechile et al., 1992). Stomas for the colon may be constructed in much the same way as end stomas for the ileum. Their suturing, however, is usually more flush than everted.

Complications of Intestinal Stomas

Complications of the abdominal stoma are the single most common problem encountered in the postoperative period after urinary intestinal diversion. Early complications of abdominal stomas include bowel necrosis, bleeding, dermatitis, parastomal hernia, prolapse, obstruction, stomal retraction, and stomal stenosis. At some point, virtually every patient has one of these complications. Many of these complications can be reduced by proper construction of the stoma. If periodic visits to the enterostomal therapist are made, products for skin care are appropriately used, nonirritative stomal adhesives are used, the urine in the collection device is maintained acidic, and properly fitting collection devices are used, most stomal complications can be significantly reduced and many eliminated.

Parastomal skin lesions may be classified as irritative, which are manifested by hypopigmentation, hyperpigmentation, and skin atrophy; erythematous erosive lesions, which appear as macular lesions, scaling of the skin, and loss of the epidermis; and pseudoverrucous, which are wartlike lesions (Borglund et al., 1988).

Stomal stenosis has been reported, on average, in 20% to 24% of patients with ileal conduits and 10% to 20% of patients with colon conduits (see Table 139.8). This incidence has been considerably reduced by better attention to stomal care and better-fitting appliances (Eisenberg et al., 2014). Stomal stenosis is less for loop stomas than for end stomas. Parastomal hernias occur rarely (1% to 4%) with end stomas but are more likely to occur with loop stomas, with reported incidences ranging from 4% to 20%. Incidence of stenosis of catheterizable stomas is high, reaching more than 50% in children (Barqawi et al., 2004). Stoma-related complications appear to be more common in an umbilically placed stoma versus one in the abdominal wall (De Ganck et al., 2002). Others have reported excellent long-term results with few complications in the concealed umbilical stoma (Glassman and Docimo, 2001).

Bleeding, stomal stenosis, and dermatitis can be markedly reduced by attention to parastomal skin care and by the use of a properly fitting appliance around a protruding stoma. The other complications are minimized by proper surgical technique.

Parastomal hernia occurs frequently after ileal loop urinary diversion, with an incidence of 2% to 6.6% (Gilbert et al., 2013). It can be effectively treated with open repair (Franks and Hrebinko, 2001; Ho and Fawcett, 2004). Laparoscopic approaches have also been reported with mixed results. One series reported a 56% failure rate within 6 months of laparoscopic parastomal hernia repair with Gore-Tex mesh (Safadi, 2004). This contrasts with the high success rates reported in other small series (Craft et al., 2008; Kozlowski et al., 2001).

Massive bleeding from the conduit occasionally occurs, usually as a result of varices. There have been several reports of patients who have developed ileal conduit varices generally as a result of hepatic dysfunction and portal hypertension. Treatment by transhepatic portal-systemic shunt and transhepatic angiography and embolization is a relatively minimally invasive technique, and its use is worthwhile in these difficult patients (Medina et al., 1998; Yao et al., 2013).

Key Points

- Principles of surgical technique for a good bowel anastomosis include: (1) obtaining adequate exposure, (2) maintaining good blood supply, (3) minimizing spillage of bowel contents, (4) apposing serosa to serosa, (5) avoiding strangulation of the bowel, and (6) aligning the mesentery of the two segments.

- Intestinal anastomoses may be performed with use of sutures or staples. Properly performed, both have similar complication rates.
- Because of its simplicity and reliability, the stapled side-to-side ileal-ileal anastomosis is the most commonly performed.
- Most complications of stomas are the result of technical errors in their construction and are the most common problem encountered after urinary diversion surgery.
- All stomas should be placed through the belly of the rectus muscle and minimize the risk for parastomal hernia.

Ureterointestinal Anastomoses

The ureter may be anastomosed to the colon or small bowel in a refluxing or nonrefluxing anastomosis. There is considerable controversy as to whether a nonrefluxing or refluxing anastomosis is desirable in urinary tract reconstruction. Regardless of type of diversion, renal failure has been seen in 12.5% of patients over the long term (Gilbert et al., 2013). Deterioration of the upper tracts for ileal and colon conduits has been reported in 10% to 60% of the patients (Koch et al., 1992; Samuel et al., 2006). In one series, 49% of the upper tracts showed changes after conduit diversion, 16% of which had an increase in blood urea nitrogen of 10 mg/dL or more (Schwarz and Jeffs, 1975). **Deterioration of the upper tracts is usually a consequence of lack of ureteral motility, infection, or stones and less commonly caused by obstruction at the ureteral-intestinal anastomosis.** Because bacteriuria occurs in almost all conduits and because the intestine certainly does not inhibit and may, in fact, promote bacterial colonization, many have suggested that a nonrefluxing anastomosis would minimize the incidence of renal deterioration.

Observations based on early studies suggested that a nonrefluxing system in urinary intestinal diversions was desirable. **In a group of patients who had nonrefluxing colon conduits constructed, those whose anastomoses remained nonrefluxing had a lesser incidence of renal deterioration than those in whom the antireflux anastomosis failed.** Follow-up for 9 to 20 years revealed that 79% (22 of 28 patients) of the refluxing renal units deteriorated, whereas only 22% (11 of 51 patients) of the nonrefluxing units deteriorated (Elder et al., 1979; Husmann et al., 1989). Others have reported that in continent diversions, the majority of patients who experience reflux show upper tract dilation and deterioration, whereas few show upper tract deterioration when a nonrefluxing anastomosis is present (Kock et al., 1978). Similar findings have been reported in experimental animals.

If a nonrefluxing ureteral-colonic conduit diversion is constructed, only 7% of the renal units show evidence of pyelonephritic scarring after 3 months. If a refluxing anastomosis is constructed, 83% of the renal units show scarring. One-half of the conduits in both groups have significant bacteriuria (Richie and Skinner, 1975). **Others, however, have not found the same high incidence of renal deterioration associated with ureteral-intestinal reflux.** One group of investigators studying colon conduits noted no difference in the incidence of renal deterioration regardless of whether the colon conduit demonstrated reflux; 17% (5 of 29) of nonrefluxing renal units showed deterioration compared with 18% (5 of 27) of refluxing units (Hill and Ransley, 1983). In another series, only 3 of 135 renal units with refluxing ureteral-intestinal anastomoses that were unobstructed showed evidence of renal deterioration (Shapiro et al., 1975). A more recent study compared refluxing and nonrefluxing ureteral-intestinal anastomoses in 58 patients with conduit diversions; 56 renal units were refluxing, and 60 renal units were nonrefluxing. There was no difference in renal deterioration or in pyelonephritis between the two groups. Ureteral-intestinal stricture formation occurred in 2% of refluxing units as opposed to 13% of nonrefluxing units (Pantuck et al., 2000). A high-capacity, low-pressure reservoir may not require antirefluxing anastomoses (Hohenfellner et al., 2002). Likewise, the complication rate and the potential for renal damage caused by obstruction of a nonrefluxing anastomosis is not justified in patients with low pressure orthotopic bladder substitutes (Studer et al., 1996).

It does not appear that conduit pressures are transmitted to the renal pelvis. The pressure within the renal pelvis in refluxing conduit diversions is not elevated above normal, and it is not dependent on the segment of bowel used (i.e., ileum or colon) (Hayashi et al., 1986; Kamizaki and Cass, 1978; Magnus, 1977). Peristaltic ureteral contractions dampen pressure transmission from intestine to renal pelvis, attesting to the importance of normal ureters. **When bowel is substituted for the ureter, it does not appear that it makes any difference whether there is reflux at the bladder.** The voiding pressure is blunted by the distensible bowel segment. Indeed, in one study of continent diversions in which a segment of ileum formed the pouch to which the ureters were anastomosed, radionuclide voiding cystography failed to detect reflux to the kidneys (Waidelich et al., 1998). Moreover, there is no difference in ileal and colon conduits between those who experience reflux and those who do not in renal function measured 2 to 5 years postoperatively (Månsson et al., 1984). **Also, the successful construction of an antirefluxing anastomosis does not prevent bacterial colonization of the renal pelvis.** In six of eight patients with nonrefluxing enterocystoplasties and one patient with a nonrefluxing colon conduit in whom the absence of reflux was documented by loopogram, percutaneous renal pelvic aspiration revealed positive cultures (Gonzalez and Reinberg, 1987). **One stated advantage of a refluxing anastomosis in patients who have urothelial cancer and are prone to malignant change is that the upper tracts may be observed by periodic introduction of contrast material**

into the conduit. From these studies, it appears that reflux associated with impaired ureteral peristalsis in the presence of bacteriuria or obstruction results in renal deterioration, but it has not been established for either conduit or continent diversions that reflux associated with the normal ureter in the absence of obstruction is detrimental to the adult kidney.

Although many techniques have been described to make the various types of ureterointestinal anastomoses, certain **basic surgical principles are germane to all the anastomoses** regardless of type. **Only as much ureter as needed should be mobilized** so that there is no redundancy or tension on the anastomosis. **Mobilization should not strip the ureter of its periadventitial tissue** because it is in this tissue that the ureter's blood supply courses. The ureter should be cleared of its adventitial tissue only for 2 to 3 mm at its most distal portion where the ureter–intestinal mucosa anastomosis is to be performed. **The ureterointestinal anastomosis must be performed with fine absorbable sutures, which are placed so that a watertight mucosa-to-mucosa apposition is constructed. The bowel should be brought to the ureter and not vice versa** (i.e., the ureter should not be extensively mobilized so that it can be brought into the wound to the bowel lying on the anterior abdominal wall). **At the completion of the anastomosis, the bowel should be fixed to the abdominal cavity, preferably adjacent to the site of the ureterointestinal anastomosis.** If possible, **the anastomosis should be retroperitonealized** or a pedicle flap of peritoneum should be placed over the anastomosis.

In those diversions in which the intestinal stoma is brought to the abdomen and the proximal end of the bowel fixed to the retroperitoneum, there are two places where the bowel may be conveniently fixed to the retroperitoneum without jeopardizing mesenteric blood supply. The most convenient point of fixation is below the root of the small bowel mesentery at the level of the pelvic brim. The ureterointestinal anastomosis may be retroperitonealized at the level of the pelvic brim, thus fixing the bowel segment to the posterior body wall. In situations in which the ureters are short, a more cephalad fixation to the posterior peritoneum may be accomplished by placing the proximal end in the right upper quadrant cephalad to the takeoff of the right colic artery and immediately below the duodenum. This is a relatively avascular area and places the intestine fairly close to the right and left kidneys, thus reducing the length of ureter required to reach the intestinal segment.

Perhaps one of the most difficult complications of ureterointestinal anastomoses to manage is a **stricture. In general, strictures are caused by**

ischemia, a urine leak, radiation, or infection. The incidence of urine leak for all types of ureterointestinal anastomoses is 3% to 5% (see Table 139.8). **This incidence of leak can be reduced nearly to zero if soft Silastic stents are used.** In one series of ureterointestinal anastomoses done at the same institution, the nonstented group had a 2% anastomotic leak and a 4% stricture rate. When non-Silastic rigid stents were used, there was a 10% incidence of stricture. When a soft Silastic stent was used, however, there were no strictures or leaks (Regan and Barrett, 1985). In a similar series in which colon conduits were constructed after gynecologic exenterative operations, the nonstented group had an 18% leak rate and an 18% stricture rate, whereas those who had been stented had a 3% leak rate and an 8% stricture rate (Beddoe et al., 1987). Early postoperative metabolic complications were reduced in a randomized study of stented versus nonstented anastomoses (Mattei et al., 2008). **Thus the evidence indicates that modern soft Silastic stents are effective in reducing the leak rate, subsequent stricture formation, and postoperative complications.** Better technique and better suture materials have also reduced the incidence of stricture in nonrefluxing anastomoses. In a series of nonrefluxing ureterocolonic anastomoses, researchers reported an 8.5% incidence of stricture formation (Stein et al., 1996b).

In constructing a submucosal tunnel in those procedures in which a nonrefluxing anastomosis is made, it is often helpful to inject saline with a 25-gauge needle submucosally to raise the mucosa away from the seromuscular layer. This makes dissection considerably easier (Menon et al., 1982).

General principles of surgical technique, such as those outlined earlier, are common to all ureterointestinal anastomoses. Each type of ureterointestinal anastomosis, however, has specific technical points unique to its construction. Techniques involving ureterocolonic anastomoses are discussed first, followed by ureter–small bowel anastomoses.

Ureterocolonic Anastomoses

Combined Technique of Leadbetter and Clarke

The combined technique of Leadbetter and Clarke establishes a nonrefluxing ureterocolonic anastomosis by using a submucosal tunnel. The technique combines the ureterocolonic anastomosis of Nesbit, which is a refluxing elliptical anastomosis to the intestine, with the tunneled technique of Coffey (Fig. 139.21) (Leadbetter and Clarke, 1954).

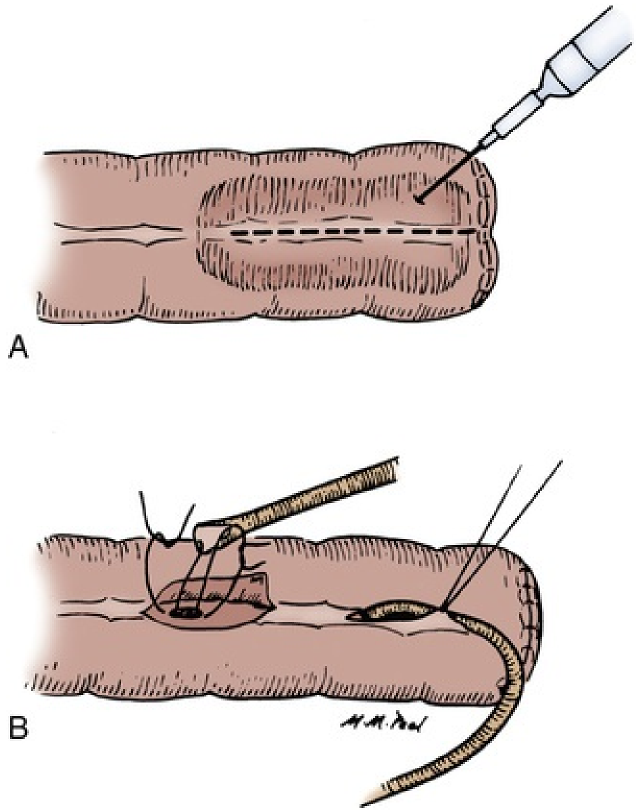

FIG. 139.21 Leadbetter-Clarke ureterointestinal anastomosis. (A) Injection of the submucosal tissues with saline facilitates the dissection. (B) A linear incision is made in the taenia, the taenia is raised, and the mucosa is identified. A small button of mucosa is removed, and the ureter is spatulated and then sutured to the mucosa with 5-0 polydioxanone sutures. The seromuscular layer is sutured over the ureter, with care taken not to compromise or occlude the ureter.

The anterior taenia is incised obliquely for 2.5 to 3 cm as close to the mesenteric border as possible. The mucosa is dissected off the muscularis for the entire length of the incision. At the distal end of the incision in the taenia, the mucosa is picked up with a fine Adson forceps, and a small button is excised. The ureter is spatulated for 5 to 7 mm such that an elliptical anastomosis may be made. The ureter is sewn mucosa to mucosa with 5-0 polydioxanone sutures (PDS) by either interrupted sutures with the knots tied on the outside or a running suture. If the suture line is to be run, it is wise to begin the anastomosis at the apex of the ureter. This suture is tied, and the posterior row is run to the most distal portion of the ureter, which is subsequently tied. A second running suture completes the anterior aspect. The seromuscular layer is then reapproximated loosely over the ureter in such a way as to allow “the ureter [to] lie in the bowel as a hammock without being compressed” (Leadbetter and

Clarke, 1954). The bowel should be fixed to the peritoneum so that there is no tension on the ureters.

The complications reported with this procedure include a leak rate of 2.5%; deterioration of the upper tracts, which varies from 4.3% to 25%; and a stricture rate that varies from 8% to 14% (Table 139.9).

Transcolonic Technique of Goodwin

The transcolonic technique of Goodwin establishes a nonrefluxing ureterocolonic anastomosis by construction of a submucosal tunnel (Fig. 139.22). By this technique, the anastomosis is performed from within the bowel (Goodwin, 1953). If it is performed in bowel in continuity with the gastrointestinal tract, a noncrushing occlusive clamp is applied across the bowel cephalad to the desired point of the ureterointestinal anastomosis. This clamp is placed loosely about the bowel so as not to occlude the arterial supply in the mesentery.

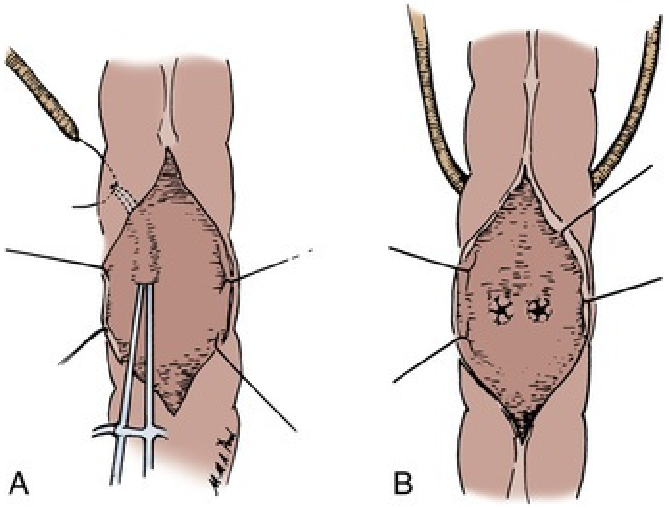

FIG. 139.22 Transcolonic technique of Goodwin. (A) The bowel is opened on its anterior surface; a small rent in the mucosa is made; and with a mosquito hemostat, the mucosa is raised from the submucosa extending laterally. A 3- to 4-cm tunnel is made before the clamp exits the serosal wall. The ureter is grasped and pulled into the submucosal tunnel. (B) Both ureters have been drawn into the bowel through their submucosal tunnels before each is spatulated and circumferentially sutured to the mucosa.

These sutures should also incorporate a portion of the muscularis for security. Where the ureter enters the colonic sidewall adjacent to the mesentery, the adventitia of the ureter is secured to the colonic serosa with interrupted 5-0 polydioxanone sutures.

A vertical incision is made in the bowel anteriorly, and the desired point of entrance of the ureter into the bowel is identified. A 0.5-cm incision is made in the posterior mucosa, and with use of a curved hemostat the mucosa is dissected from the submucosal layer in an oblique fashion coursing from medial to lateral. The hemostat is passed beneath the mucosa for a distance of approximately 3 to 4 cm and then brought through the serosa. A traction suture that has been placed on the ureter is then grasped with the hemostat, and the ureter is brought into the colon. Both ureters should be brought into the bowel before they are sutured to the mucosa. The ureters should lie without tension or angulation. A No. 5 feeding tube is passed through the ureter to be sure that there is no kinking as it passes through the bowel wall. The redundant ureter is excised, and its end is spatulated and sewn with interrupted 5-0 PDS to the mucosa, with care taken to include with the mucosa some muscularis so that the ureter is securely fixed in place. A Silastic stent is placed up both ureters. As the ureters come through the serosa from without the bowel, the adventitia of the ureter is sutured to the serosa of the colon with two 4-0 PDS. The anterior bowel wall is closed in two layers.

The reported results with this technique appear to be satisfactory. However, specific reliable data on the complication rate are not available.

Strickler Technique

The Strickler technique establishes a nonrefluxing ureterocolonic anastomosis by construction of a submucosal tunnel (Fig. 139.23) (Jacobs and Young, 1980; Strickler, 1965). A 1-cm incision is made on the margin of the taenia. The technique originally described removal of a 2-mm button of seromuscular tissue. A 2-cm tunnel is formed laterally beneath the seromuscular layer with a hemostat. The seromuscular layer is incised, with care taken not to tent up the mucosa and inadvertently incise it. The holding suture in the ureter is grasped and drawn throughout the submucosal tunnel. The ureter is spatulated for 0.5 cm. A button of mucosa is removed, and the full thickness of the ureter is sewn to the mucosa of the bowel with either interrupted or running 5-0 PDS. The serosa is reapproximated over the ureter with 4-0 silk sutures. The serosal suture line is perpendicular to the course of the ureter. Where the ureters enter the serosa, they are also fixed with interrupted 4-0 PDS. A lateral peritoneal flap is placed over the anastomosis.

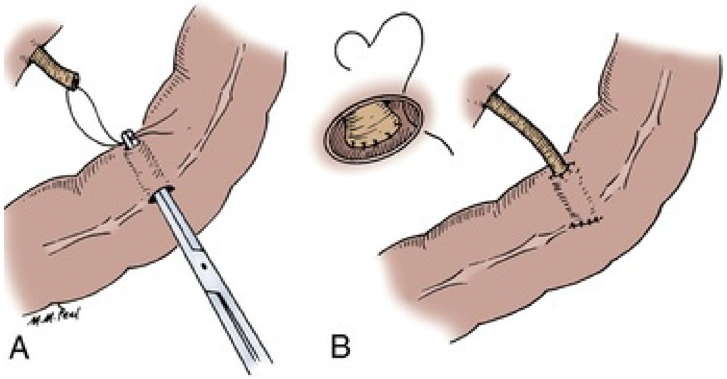

FIG. 139.23 Strickler ureterointestinal anastomosis. (A) A small linear incision is made in the taenia, and the submucosa is dissected from the mucosa laterally. After a distance of 3 to 4 cm has been achieved, a small hole is made in the serosa and the ureter is drawn through. (B) A button of mucosa is excised, and the ureter is spatulated and sutured to the mucosa with 5-0 polydioxanone sutures. The rent in the taenia is closed with interrupted sutures, and an adventitial suture at the ureter's entrance point into the colon secures it to the serosa of the colon.

The advantage of this anastomosis is that because the taeniae do not need to be aligned, one can form the tunnel according to the normal course of the ureter and avoid angulation. This technique reliably prevents reflux but results in a stricture rate of approximately 14% (see Table 139.9).

Pagano Technique

The Pagano technique establishes a nonrefluxing ureterointestinal anastomosis by construction of a submucosal tunnel (Fig. 139.24) (Pagano, 1980). The taenia is incised for a length of 4 to 5 cm, and the seromuscular layer is separated from the mucosa on both sides of the taenia laterally as far as the mesenteric border. The ureter is brought in one end (i.e., the distal end) laterally and laid in the 4- to 5-cm tunnel paralleling the mesenteric border. A button of mucosa is excised, and the ureters are spatulated and sutured to the mucosa with either interrupted or running 5-0 PDS. The seromuscular layer is then closed loosely with silk sutures in the midline. Each suture includes the seromuscular layer of the taenia and the mucosa in the midline.

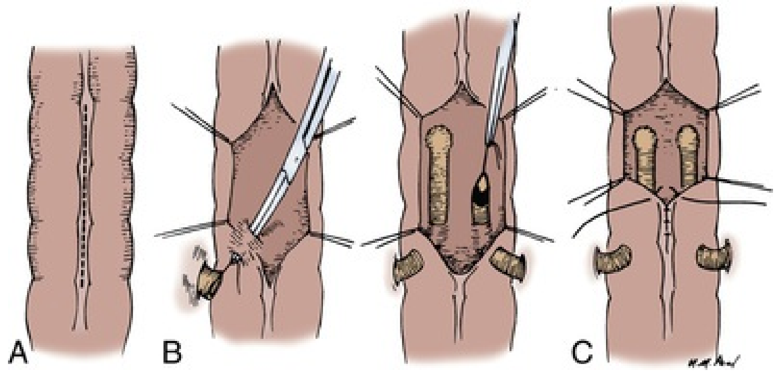

FIG. 139.24 Pagano ureterointestinal anastomosis. (A) A linear incision is made in the taenia between 4 and 5 cm in length. (B) The submucosa is dissected from the mucosa laterally on both sides to the level of the mesentery. The ureters are drawn into the submucosal tunnel distally and sutured to the mucosa with 5-0 polydioxanone sutures proximally. (C) The serosa is reapproximated, with incorporation of the mucosa in the midline.

This technique has a reported low complication rate. The leakage rate is approximately 3%, the stricture rate is 6%, and the reflux rate is approximately 6% (see Table 139.9) (Pagano et al., 1984).

Cordonnier and Nesbit Techniques

The Cordonnier and Nesbit techniques use no tunnel and are direct refluxing anastomoses of the ureter to the colon (Cordonnier, 1950; Nesbit, 1949). They are not desirable for ureterosigmoidostomies. They are performed in much the same way as a Bricker anastomosis would be performed for the small bowel (see later).

Small Bowel Anastomoses

There is a variety of ureter–small bowel anastomoses, which are of two basic types: end to side, and end to end. The end-to-side anastomoses may be constructed in a refluxing or nonrefluxing manner.

Bricker Anastomosis

The Bricker anastomosis is a refluxing end-to-side ureter–small bowel anastomosis that is simple to perform and has a low complication rate (Fig. 139.25) (Bricker, 1950). Although originally described for the small bowel, it may be used in any suitable intestinal segment.

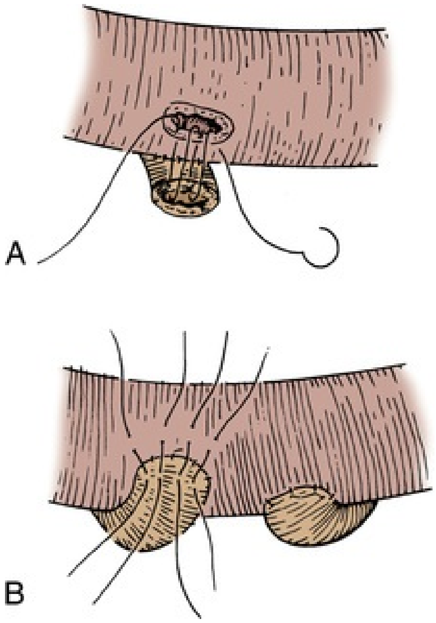

FIG. 139.25 Bricker ureterointestinal anastomosis. (A) The adventitia of the ureter is sutured to the serosa of the bowel. A small full-thickness serosal and mucosal plug is removed. Interrupted 5-0 polydioxanone sutures approximate the ureter to the full thickness of the mucosa and serosa. (B) The anterior layer is completed by interrupted sutures placed through the adventitia of the ureter and the serosa of the small bowel.

In the original description, the adventitia of the ureter was sutured with interrupted silk sutures to the serosa of the bowel. The mucosa and serosa were incised; a small mucosa plug was removed; and with fine absorbable chromic sutures, the full thickness of the ureter was sewn to the mucosa of the bowel. The anterior layer of ureteral adventitia was then sewn with interrupted silk sutures to the serosa of the bowel. A less cumbersome method of performing this anastomosis is to excise a small button of seromuscular tissue and mucosa, spatulate the ureter for 0.5 cm, and suture the full thickness of the ureter to the full thickness of the bowel (i.e., mucosa and seromuscular layer to ureteral wall) with either interrupted or running 5-0 PDS. The anastomosis is stented with a soft Silastic stent.

The stricture rate for this anastomosis varies from 4% to 22% (average of 6%). The leak rate is approximately 3% in the absence of stents (see Table 139.9). Open and robotic approaches have a comparable stricture rate (Anderson et al., 2013).

Wallace Technique

A frequently used anastomotic technique is that of Wallace, in which the end of the intestine is sutured to the end of the ureter (Fig. 139.26) (Albert and Persky, 1971; Wallace, 1970). This is a refluxing anastomosis. The intestinal segment used may be either small bowel or colon. There are three basic types of anastomoses:

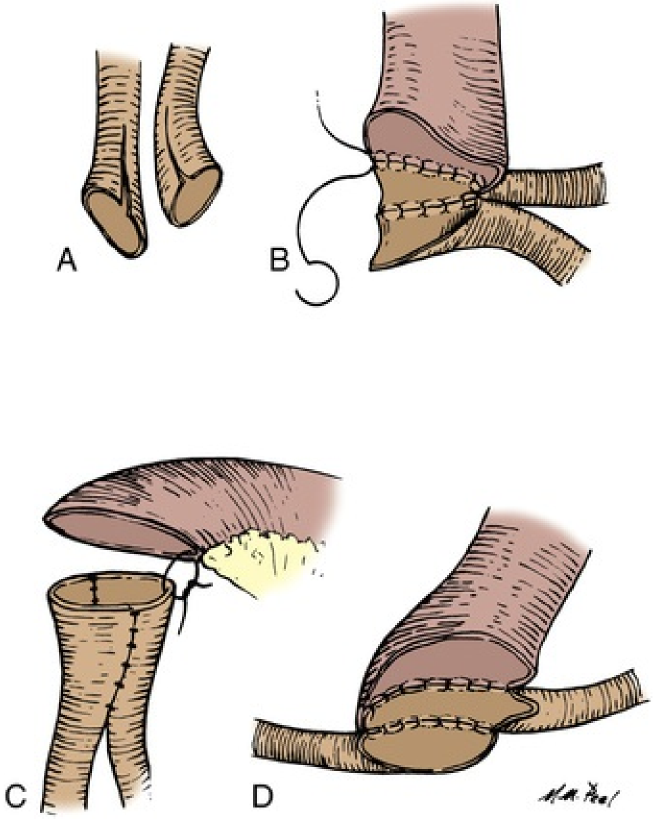

FIG. 139.26 Wallace ureterointestinal anastomosis. (A) Both ureters are spatulated and laid adjacent to each other. (B) The apex of one ureter is sutured to the apex of the other ureter with 5-0 polydioxanone sutures (PDS). The posterior medial walls of both ureters are then sutured together with interrupted or running 5-0 PDS, the knots tied to the outside. The lateral ureteral walls are then sutured to the intestine. (C) A *Y*-type anastomosis is formed by completing the anterior row of the anterior lateral ureteral walls of the ureters as shown in (B) and then suturing the ends of the ureters directly to the intestine. (D) The head-to-tail anastomosis involves suturing the apex of one ureter to the end of the other. The posterior medial walls are sewn together, and then the ends and lateral walls are sewn to the intestine.

1. The end of one ureter is sutured to the end of the other ureter, and this composite anastomosis is sutured to the end of the bowel.

2. A Y anastomosis of the ureters is constructed and sutured to the end of the bowel.
3. A head-to-tail ureteroureteral anastomosis is formed, which is then sutured to the end of the bowel.

The ureters are spatulated for 1.5 to 2 cm, and fine 5-0 PDS are used for each anastomosis.

For the first anastomosis, a fine suture is placed at the apex of each ureter with the knot tied to the outside. The posterior medial ureteral walls are sutured together, and the anterior lateral walls are sutured directly to the bowel with interrupted 5-0 PDS. Where the suture line of the end of the ureters comes to the bowel, a horizontal mattress suture is placed to make the anastomosis watertight. If a Y type of anastomosis is desired, after the posterior ureteral walls have been sutured together as described earlier, the anterior walls of the ureters are sutured together and the end of the composite anastomosis is sutured to the bowel. Again, where the suture lines meet the bowel, a horizontal mattress suture is placed so that the anastomosis is watertight. The head-to-tail anastomosis involves suturing the end of one ureter to the apex of the other. The posterior medial walls of the two ureters are approximated. The anterior lateral walls are sutured to the bowel.

The Wallace anastomosis has the lowest complication rate of any of the ureterointestinal anastomotic techniques. The incidence of stricture formation is approximately 3%, of deterioration of the upper tracts is about 4%, and of leakage is about 2% (see Table 139.9). Historically, the Wallace technique was not recommended for patients who have extensive carcinoma in situ or a high likelihood of recurrent tumor in the ureter out of concern that a recurrence of tumor at the anastomotic line in one ureter would block both ureters. This, however, is exceedingly rare. **A Wallace anastomosis may actually be easier to survey endoscopically** because both ureters can be easily found next to each other at the most proximal portion of the loop. **Additionally, it has a lower rate of obstruction than a Bricker anastomosis** (Kouba et al., 2007).

Tunneled Small Bowel Anastomosis

The tunneled small bowel anastomosis method attempts to establish a nonrefluxing anastomosis by construction of a submucosal tunnel (Fig. 139.27) (Starr et al., 1975). Two 0.5-cm incisions are made in the serosa on the antimesenteric border 2.5 cm apart at right angles to the long axis of the bowel.

The seromuscular layer is then gently separated from the mucosa with a blunt hemostat. The ureter is pulled through one incision, a button of mucosa is removed over the other incision, and the ureter is spatulated and sutured to the mucosa with interrupted 5-0 PDS. The serosa is then closed with interrupted 4-0 silk sutures, and the adventitia of the ureter is sutured at its entrance through the serosa of the bowel to the serosa.

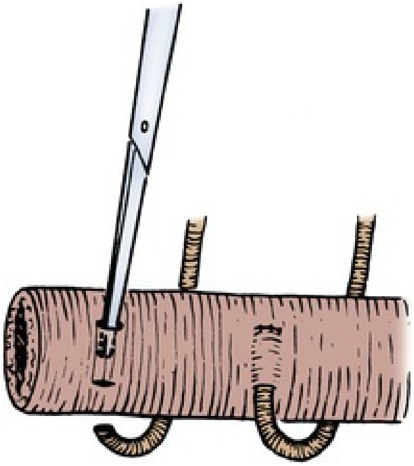

FIG. 139.27 Tunneled small bowel anastomosis. A small transverse incision is made in the small bowel, and a second transverse incision 3 cm lateral to it is also made. The submucosal tunnel is made, a button of mucosa is removed, and the ureter is drawn through the tunnel and sutured directly to the mucosa. The rent in the serosa is closed, and an adventitial ureteral suture is placed and secured to the serosa at the ureter's entrance to the small bowel.

Good results have been reported, but this technique has not been widely used. Therefore long-term follow-up is not available (Osman et al., 2004).

Split-Nipple Technique

The split-nipple technique attempts to establish a nonrefluxing anastomosis by using a nipple mechanism. It may be applied to either the small or large bowel. This technique was described by Griffiths and involves formation of a nipple in the ureter and implantation into the small bowel (Fig. 139.28) (Warwick and Ashken, 1967). A 0.5-cm longitudinal incision in the ureter is made, and the ureteral wall is turned back on itself, constructing a nipple at least twice as long as its width. The cuff is stabilized at the corners with sutures. A button of seromuscular and mucosal tissue is removed, and the ureter is then placed into the bowel such that it protrudes through the mucosa. The adventitia just proximal to the point where the ureter has been sewn to itself is sutured to the full thickness of the bowel wall with interrupted 5-0 PDS. The anastomosis is stented.

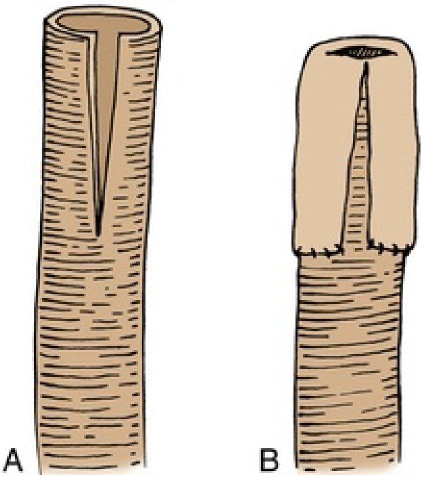

FIG. 139.28 (A and B) Split-nipple technique. The ureter is spatulated and turned back on itself, and the end of the ureter is secured to the adventitia of the ureter with interrupted 5-0 polydioxanone sutures.

In one series, this type of anastomosis prevented reflux in more than 50% of the patients. In subsequent series, approximately 80% of patients had a nonrefluxing anastomosis with an acceptably low incidence of stenosis (see Table 139.9). There is a stricture rate of about 7% (De Carli et al., 1997).

Le Duc Technique

The Le Duc method establishes a nonrefluxing anastomosis by laying the ureter onto the interior of the bowel wall, eventually resulting in a submucosal tunnel when it is re-epithelialized (Fig. 139.29) (Le Duc et al., 1987). This technique has been used to prevent reflux in the ureter–small intestine anastomosis. Excellent exposure is required, and therefore the small bowel needs to be opened along its antimesenteric border for a length of approximately 5 cm. The mucosa is incised for a length of 3 cm beginning 2 cm proximal to the cut edge of the bowel. It is important to begin the mucosal tunnel away from the cut edge of the bowel to allow enough distal bowel for closure without jeopardizing the entrance point of the ureter. The ureter is then brought through the serosa at the most distal portion of the mucosal sulcus, laid in the trough, spatulated, and sutured to the proximal end of the sulcus with interrupted 5-0 PDS using the full thickness of ureteral wall and anchored to the muscularis and mucosal layers of the bowel. The mucosa of the sulcus of the bowel is then sutured to the adventitia of the ureter. The mucosa of the bowel should not be sutured over the ureter but rather to its lateral aspect. The idea is that the mucosa eventually grows over the top of the ureter. Where the ureter enters the small bowel, its adventitia is sutured to the bowel serosa with 4-0 silk sutures. Stents are placed in the ureter, and their passage must be unimpeded to ensure that there is no angulation. The bowel should be fixed to the body wall near the site of the ureteral implantation so that the ureters do not angulate.

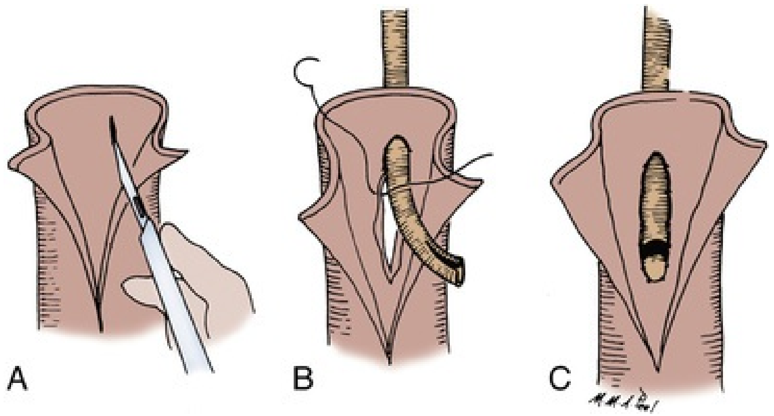

FIG. 139.29 Le Duc ureterointestinal anastomosis. (A) The small bowel is opened for approximately 4 to 5 cm. A longitudinal rent in the mucosa is made, and the mucosa is raised. (B) At the distal end of the mucosal rent, a hole is made in the serosa, and the ureter is then drawn through. The entrance of the ureter through the serosa should be at least 2 cm proximal to the cut end of the bowel to allow sufficient bowel length to close the end. (C) The ureter is spatulated and sutured to the mucosa and muscle layers. The mucosa is not reapproximated over the top of the ureter but rather sutured to the side of it.

The complication rate for this technique is relatively low, although the follow-up is also relatively short. Initial reports suggested that it carried with it an 87% incidence of maintaining an antireflux valve with a 5% incidence of stricture and a 2% incidence of leak (Schwaibold et al., 1998). A modification of the Le Duc technique was prompted by a 15% incidence of stricture when longer follow-up was available. With the modified technique, the stricture rate was 3% with 2.5 years of follow-up. The technique involves construction of a 3-cm mucosal sulcus to the submucosa. The ureter is brought in the proximal sulcus transmurally and anchored to the serosa externally. The ureter is spatulated for 1.5 cm, and only the spatulated portion is sewn to the muscularis of the bowel. The proximal intraluminal ureter is not fixed to the bowel (see Table 139.9).

Hammock Anastomosis

The hammock anastomosis involves conjoining the ureters and implanting them into the small bowel in a nonrefluxing manner. The small bowel is closed at its proximal end, and three 10-cm longitudinal incisions separated by 1 to 2 mm are made through the seromuscular layer to the mucosa. These incisions are cross-hatched by multiple incisions. This serves as a hammock. The ureters are conjoined as in the Wallace technique and sutured to the intestinal mucosa. The ureters are buried by closing the intestinal wall over the top of them with seromuscular sutures of 3-0 polyglycolic acid suture (Hirdes et al., 1988).

With this technique, there is a 6% incidence of ureteroileal stenosis and approximately a 20% incidence of reflux. Follow-up, however, is relatively short.

Ureteral Dipping Technique

Described in 640 patients who underwent continent urinary diversion, the dipping technique is relatively simple to perform and has excellent success (Wishahi et al., 2013). Wishahi et al. form the neobladder, and then make a small opening in the small bowel wall. The ureter is “dipped” approximately 1 cm into the bladder cavity and then secured to the seromuscular portion of the bowel. No mucosal anastomosis is performed. The long-term success of renal preservation reported deserves further investigation.

Ureter–Small Bowel Anastomosis Using Serosal Compression of the Extramural Ureter as an Antireflux Mechanism

Primarily applicable to a continent diversion in which detubularized small bowel is used and an antireflux ureterointestinal anastomosis is desired, ureter–small bowel anastomosis involving serosal compression of the extramural ureter requires two segments of small bowel to be juxtaposed. The ureter is laid between the two small bowel serosal surfaces, which are sutured posterior and anterior to the extramural portion of the ureter. The technique is described in the following sections.

The posterior wall of the extramural tunnel is composed of the two segments of small bowel sutured together with 3-0 silk sutures (Fig. 139.30A and B). The two segments of small bowel are opened along their antimesenteric borders. The ureter is spatulated and sutured to the mucosal-seromuscular layer with 5-0 absorbable sutures. The edges of the opened small bowel are then reapproximated over the anterior ureter with absorbable sutures (see Fig. 139.30C), thus making a serosal tunnel 4 cm in length. When the bowel is distended, it then applies pressure to the extramural ureter, thus preventing reflux (Abol-Enein and Ghoneim, 1994).

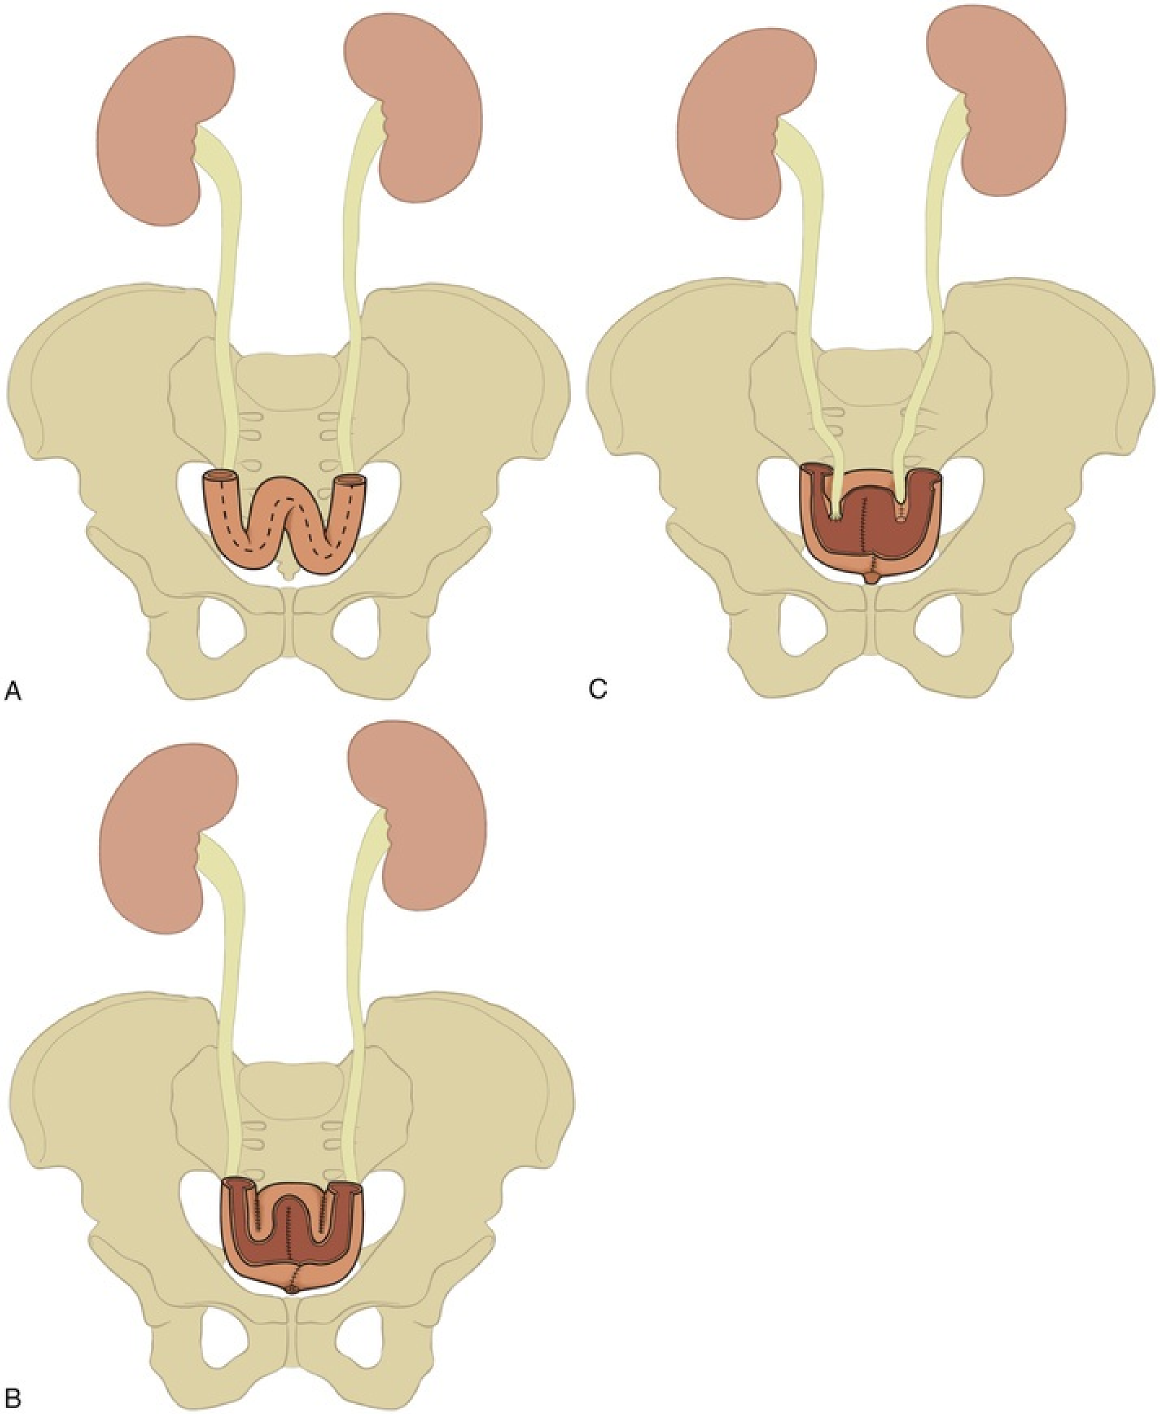

FIG. 139.30 Ureter–small bowel anastomosis. (A) Small bowel aligned so that four serosal surfaces are apposed in preparation for construction of two serosal compression tunnels. Serosal surfaces of the afferent limbs adjacent to the mesentery are sutured together with silk sutures. (B) The serosal surfaces of the afferent limbs adjacent to the mesentery are sutured together with silk sutures. The antimesenteric borders of the apposed bowel segments are opened, thus making a trough. (C) The ureters are laid in the trough and sutured to the seromuscular-mucosal wall

at its distal end (illustrated on the right ureter), and the seromuscular-mucosal layer is closed over the ureter anteriorly (illustrated on the left ureter).

With an average of 3 years of follow-up, the anastomotic stricture rate is 4%, and the rate of failure of the antireflux mechanism is 3% (Abol-Enein and Ghoneim, 2001; Türkölmez et al., 2004).

Intestinal Antireflux Valves

Another technique for preventing reflux into the ureter involves construction of an antireflux mechanism with bowel distal to the ureterointestinal anastomosis. The ureter is sutured by the technique of either Bricker or Wallace (as described earlier) to the end of the bowel, and the bowel is used to make a one-way valve. Unlike with individual ureterointestinal antirefluxing anastomosis, when these valves fail or stenose, both kidneys are affected. Three basic types of antireflux mechanisms commonly used with the bowel are ileocecal intussusception, ileoileal intussusception, and ileal nipple valve placed into colon.

Intussuscepted Ileocecal Valve

The mesentery is cleared from the ileum for a length of 8 cm beginning at the cecum and coursing proximally (Fig. 139.31). At least 5 cm of ileum proximal to the detached mesentery must be intact to ensure intestinal viability. Thus the ileum should not be transected less than 13 cm from the ileocecal junction. A No. 22 catheter is placed through the ileum into the cecum. The ileal serosa is scarified either by multiple cross-incisions with a knife or with the electrocautery unit. The 8-cm segment is intussuscepted over the catheter into the cecum. The intussuscepted ileum is secured to the cecal wall with 3-0 silk sutures placed circumferentially 2 mm apart.

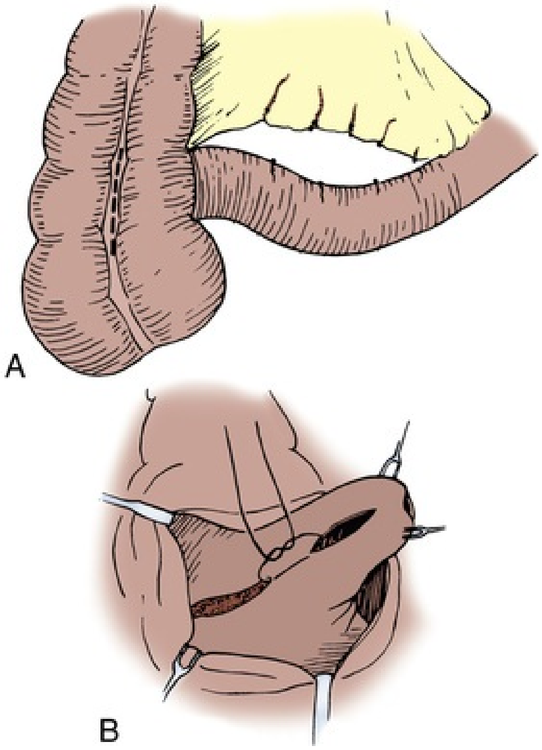

FIG. 139.31 Ileocecal intussusception. (A) An 8-cm segment of ileal mesentery is cleared from the serosa beginning at the ileocecal junction. At least 5 cm of mesentery remains attached to the proximal ileum. An incision is made along a taenia at the level of the ileocecal valve. (B) The ileum is intussuscepted over a 22-Fr catheter into the cecum under direct vision. The mucosa of the intussuscepted segment is incised, and the mucosa of the cecum adjacent to it is also incised. The muscle coats of both segments are sutured together. The serosa of the ileum is secured to the serosa of the cecum with interrupted 3-0 silk sutures placed circumferentially *(not depicted).*

The valve has a moderate tendency to fail because the intussusception has a significant chance of reduction. In one series, the antireflux mechanism remained intact in 55% of the patients during the long term (Hensle and Burbige, 1985). The intussusception may be made more secure by using a modification described by King (1987). The mesentery is cleared as described earlier. The cecum is opened along a taenia, and the ileum is intussuscepted over the catheter under direct vision. Where the intussusception lies adjacent to the cecal wall, mucosa of the intussuscepted ileum and the cecal mucosa adjacent to it are incised down to muscle. The muscles are sewn together with interrupted 3-0 chromic sutures. Long-term follow-up in eight patients reveals maintenance of the antireflux valve in seven with the modified technique (Friedman et al., 1992; King, 1987). The Mainz group advocates stapling the intussuscepted ileum to the ileocecal valve to prevent reduction. In their series, 82% of patients maintained valve competence; however, there was a 20% incidence of stone formation (Wiesner et al., 2006).

Intussuscepted Ileal Valve

The mesentery is cleared from an 8-cm segment of ileal serosa (Fig. 139.32). There must be 5 cm of ileal mesentery proximal and distal to the cleared segment to ensure proper blood supply. The ureters are sewn to the proximal end of ileum. The distal end of ileum is opened along its antimesenteric border to within 2 to 3 cm of the cleared mesentery to provide adequate exposure and direct visualization of the intussuscepted segment. A Babcock clamp is placed into the lumen of the bowel, and a portion of bowel wall is grasped by invaginating it into the clamp with a finger. The ileal segment is intussuscepted by pulling on the Babcock clamp with gentle constant traction. If there is resistance, the mesentery is usually too bulky, and it must be defatted carefully before another attempt to intussuscept the segment. A 5-cm intussuscepted segment should protrude. The gastrointestinal stapler without the knife or the linear stapler, from which the distal five to eight staples have been removed, is used to secure the intussusception in place; three rows with the gastrointestinal stapler or four rows with the linear stapler are placed in quadrants. The staple size should be 4.8 mm. The proximal staples are important in securing the intussusception and preventing its reduction, whereas the distal staples are less effective and more likely to be exposed to urine and thus facilitate stone formation. It is for this reason that the distal staples are removed from the staple cartridge before it is placed in the stapler and before the intussusception is stapled. With the cautery unit, the mucosa of the intussusception is incised along its length. Adjacent to this incision, another is made in the mucosa of the ileum. The muscularis of both is exposed and sewn together with interrupted 3-0 chromic suture. The distal serosa is then sutured proximally to the serosa of the intussuscepted segment circumferentially with 3-0 nonabsorbable sutures. This is meant to secure the intussusception and to prevent its reduction with failure of the antireflux mechanism. The valve is successful in preventing reflux 90% of the time (Kock et al., 1982; Skinner et al., 1989).

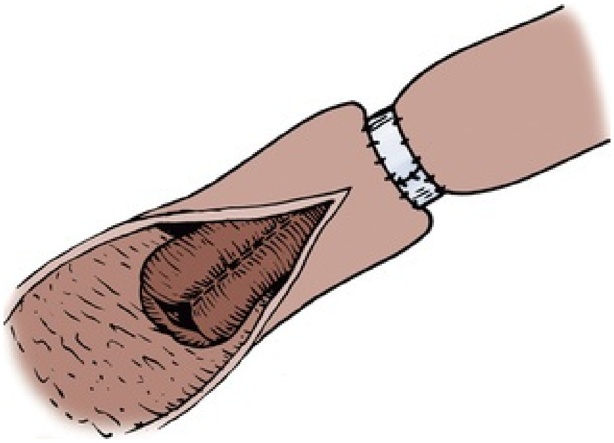

FIG. 139.32 Intussuscepted ileal nipple valve. An 8-cm length of ileal mesentery is cleared from the serosa. The ileum distally is opened within 2 to 3 cm of the rent in the mesentery; a 5-cm length of ileum is intussuscepted and secured by placement of staples in quadrants. The ileal mucosa is incised adjacent to an incision in the intussuscepted segment, and the two muscle coats are sutured together with interrupted 3-0 chromic suture. The serosa of the intussuscepted segment is sutured circumferentially to the base of the ileum, into which the proximal segment is intussuscepted with interrupted silk suture.

Because the intussuscepted nipple valve as an antireflux mechanism has resulted in a 10% complication rate (5% stone formation on the exposed staples, 4% stenosis, and 1% prolapse) (Stein et al., 1996a), modifications have been developed in an attempt to reduce these untoward outcomes. One such modification has been described by the University of Southern California group. An 8- to 10-cm isolated segment of ileum is tapered distally and laid between two segments of small bowel in which their serosal walls adjacent to the mesentery are sutured together. This serves as the posterior support for the isolated segment. The apposed bowel is opened along its antimesenteric border; lateral flaps are constructed adjacent to the segment and closed over its anterior aspect, thus making a serosal trough in which 4 cm of the segment of tapered ileum is positioned (Stein and Skinner, 2003). When the pouch is closed, a nipple valve is constructed. The concept is that as pressure in the pouch increases, the walls of the tapered nipple valve are compressed, thus preventing reflux. The authors call their modification a *T pouch.*

Nipple Valve

The simplest intestinal antireflux valve to make is the nipple valve with use of ileum (Fig. 139.33). The mesentery is cleared from the last 8 cm of the cut end of the ileum. The distal 6 cm of serosa is scarified by multiple cross-striations and then turned back on itself to form a nipple. The nipple should be at least 4 to 4.5 cm in length. The end of the inverted ileum is then sutured to itself with interrupted 4-0 PDS. An incision on the taenia large enough to accommodate the segment is made. A No. 22 catheter is placed through the segment, and its serosa is sutured to the colon serosa circumferentially with interrupted 3-0 silk sutures placed 2 mm apart. The long-term success rate for this type of valve is unknown but is comparable to tunneled anastomoses (Osman et al., 2004).

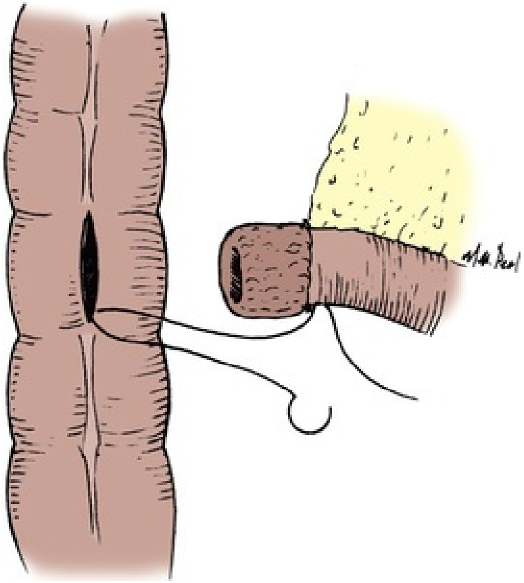

FIG. 139.33 Nipple valve. Approximately 8 cm of mesentery are cleared from the distal end of the ileum, and the serosa is scarified and then turned back on itself to form a nipple of approximately 4 cm in length. The end of the ileum is sutured to itself with interrupted 4-0 polydioxanone sutures (PDS). A rent is made in the colon through a taenia, and the nipple valve is placed through the rent and secured with circumferential interrupted 4-0 PDS through the full thickness of the colon and the seromuscular layer of the ileum.

Complications of Ureterointestinal Anastomoses

The complications that occur with ureterointestinal anastomoses include leakage, stricture, reflux in those anastomoses that were performed to prevent reflux, and pyelonephritis. In a review of the various types of procedures, it appears that of the colonic antirefluxing procedures, the **Pagano technique** offers the lowest incidence of stricture with an acceptable incidence of reflux. With respect to small bowel antireflux procedures, the **Le Duc procedure** and the ureterointestinal serosal apposition procedure seem to offer the lowest incidence of stricture with the highest success rates in preventing reflux. With respect to stricture formation and leakage, it appears the **Wallace technique** has the best results (Kouba et al., 2007).

Urinary Fistula

Urinary fistulas typically occur within the first 7 to 10 days postoperatively with an incidence of 3% to 9% (see Table 139.9) (De Nunzio et al., 2013; Loening et al., 1982)**. The incidence of urinary intestinal leak is markedly reduced by the use of soft Silastic stents** (Mattei et al., 2008). A urinary intestinal leak may cause periureteral fibrosis and scarring with subsequent stricture formation.

Stricture

In general, **the antirefluxing techniques have a higher incidence of stricture.** Patients are at risk for ureterointestinal strictures for the life of the anastomosis and must be observed on a scheduled periodic basis. A stricture has been reported to develop 13 years after the procedure (Shapiro et al., 1975). **Ureteral strictures also occur away from the ureterointestinal anastomosis. This stricture is most common in the left ureter and is usually found as the ureter crosses over the aorta beneath the inferior mesenteric artery.** It has been suggested that this occurs because of overly aggressive stripping of adventitia and angulation of the ureter at the inferior mesenteric artery.

Once a stricture has developed, various techniques may be used to rectify the situation. The most successful is re-exploration, with removal of the stenotic segment and reanastomosis of the ureter to the bowel by one of the aforementioned techniques. A number of studies have compared open surgical correction of ureterointestinal anastomotic strictures with endourologic methods. In general, **open repair has a success rate of approximately 75% at 3 years versus 15% for balloon dilation** with similar follow-up (DiMarco et al., 2001). Open surgical methods may be morbid and difficult procedures. Endourologic procedures using balloon dilation have not proved to be durable, and therefore many surgeons have used either cold knife incisions or laser incisions. **When several series involving use of endourologic methods are combined, there is a 50% to 60% success rate** with 2 years of follow-up. **Strictures occurring in**

less than 1 year from the original procedure, strictures 1.5 cm or longer, and left-sided strictures have less favorable outcomes with endourologic methods (Cornud et al., 1996; Kramolowsky et al., 1987, 1988; Laven et al., 2001; Poulakis et al., 2003). These data must be viewed with caution because longer follow-up usually results in additional recurrences. Metal stents may be considered in a patient with a limited life expectancy, thus avoiding a major open operation; however, such stents should be used with caution in the case of ureteral stricture. In one study utilizing the Resonance metallic ureteral stent (Cook Medical, Bloomington, IN) stricture patency was preserved in only in 8 of 18 cases (44%) at a mean follow-up time of just 2.6 months (Liatsikos et al., 2010). Self-expanding metal alloy stents (Wallstents, Schneider, Zurich, Switzerland) showed more promising results in a small trial of nonmalignant ureterointestinal strictures with successful treatment of 10/10 strictures at a median follow up of 22 months; one patient developed a stone on the stent (Palascak et al., 2001). Additional long-term studies are needed.

Pyelonephritis

Acute pyelonephritis occurs both in the early postoperative period and during the long term. Its incidence is approximately 10% to 20% in patients diverted with ileal conduits and 9% in those diverted with antirefluxing colon conduits (see Table 139.8). **These complications cause considerable morbidity and, in fact, are associated with significant mortality.** In one series of intestinal segments in the urinary tract, 8 of 178 patients died of sepsis (Schmidt et al., 1973). That these complications may result in delayed mortality is indicated by the fact that 2 of 115 children and 3 of 127 adults died of septic complications 5 to 14 years after intestinal diversion (Pitts and Muecke, 1979). **When sepsis is associated with decreasing renal function and uremia, the morbidity and mortality are markedly increased.** Although the mortality rate may be somewhat lower in the current age of antibiotics, the rise of multidrug-resistant organisms poses a significant threat in both the short and long term in patients undergoing urinary diversion.

Table 139.9 summarizes the complications and success rates for the various types of anastomoses. The table is derived from composite reports in the literature in which specific anastomoses were described and from which the data could be accurately analyzed. Because of these two requirements, it is not possible to comment, for example, on the incidences of reflux or leakage among various anastomotic types inclusively. These complications can be minimized by adherence to the principles of ureterointestinal surgery discussed earlier.

Renal Deterioration

The incidence of renal deterioration after conduit urinary intestinal diversion has varied from 10% to 74% (Eisenberg et al., 2014; Gilbert et al., 2013; Madersbacher et al., 2003). This variance is perhaps a result of the fact that many reports include both renal units that were abnormal and those that were normal before diversion. **In analyzing abnormal renal units before diversion and documenting progressive disease, it is difficult to be sure whether the urinary diversion caused the progression or whether progression is caused by the intrinsic abnormality for which the diversion was constructed. When the incidence of renal deterioration is determined by comparing renal units that were normal before diversion and then deteriorated postoperatively, 18% of patients who have ileal conduits show progressive deterioration versus 13% who have nonrefluxing colon conduits** (see Table 139.8). Twenty percent of patients with nonrefluxing continent ileocecal bladders show some evidence of deterioration of the upper tracts when they are observed during the long term (Benchekroun, 1987). This deterioration leads to a 10% incidence of azotemia in children with ileal conduits (Schwarz and Jeffs, 1975) and a 12% (5 of 41 patients) incidence of renal failure in patients with colon conduits constructed for benign disease (Elder et al., 1979). **There is significant and progressive deterioration in renal function in the majority of patients independent of the type of urinary diversion** (Eisenberg et al., 2014).

The incidence rates for both sepsis and renal failure are greater in patients with ureterosigmoidostomy than in those with conduits. Sepsis and renal failure may occur either in the immediate postoperative period or many years later. **The most common cause of death in patients who have had a ureterosigmoidostomy for more than 15 years is acquired renal disease (i.e., sepsis or renal failure).** In this group of patients, approximately 10% to 22% die of these disorders (Zabbo and Kay, 1986), some as late as 27 years after diversion (Mesrobian et al., 1988). **In patients with ileal conduits, about 6% ultimately die of renal failure** (Richie, 1974).

Renal Function Necessary for Urinary Intestinal Diversion

The amount of renal function required to effectively blunt the reabsorption of urinary solutes by the intestinal segment and to prevent serious metabolic side effects depends on the type of urinary intestinal diversion constructed (i.e., the amount of bowel to be used and the length of time the urine is exposed to the intestinal mucosa). Thus **a greater degree of renal function is necessary for retentive (continent) diversions than for short conduit diversions.** In general, patients who have a glomerular filtration rate (GFR) on average above 40 mL/min tolerate a continent diversion reasonably well. Indeed, in one study, two groups of patients were analyzed: those with GFRs around 100 mL/min (range, 91 to 112) and those with GFRs around 55 mL/min (range, 36 to 69). Both seemed to tolerate the metabolic load well with a minimal development of metabolic acidosis. There was a slightly increased incidence of metabolic acidosis in the group with low GFR, as would be expected; however, in this group, distal tubule function was excellently maintained as demonstrated by ammonium chloride loading. This observation points out that GFR is not the sole determining factor that allows the body to manage intestinal diversion. Indeed, GFR is but one factor. Just as important is distal tubule function. This article confirms that when distal tubule function is normal and the GFR is above 40 mL/min, patients do extremely well (Kristjánsson et al., 1997).

There are five components of renal function: renal blood flow, glomerular filtration, tubule transport, concentration and dilution, and glomerular permeability. Aspects of renal function that must be specifically addressed are GFR, best measured by inulin clearance; ability of the tubule to acidify, determined by ammonium chloride loading; concentrating ability, determined by water deprivation; and glomerular permeability, reflected by urine protein concentrations. **In general, patients with normal urine protein content who have a serum creatinine concentration below 2.0 mg/dL do well with intestine interposed in the urinary tract.** Serum cystatin C is a promising serum protein that reflects GFR more accurately than creatinine; however, its usefulness in urinary intestinal diversion has not yet been determined (Herget-Rosenthal et al., 2012; Inker et al., 2012). At a level of serum creatinine below 2 mg/dL, renal blood flow, GFR, tubule transport, and concentrating and diluting ability are relatively well preserved. **In patients whose serum creatinine concentration exceeds 2 mg/dL and who are being considered for retentive diversion or in whom long segments of intestine will be used, a more detailed analysis of renal function is necessary. If the patient can achieve a urine pH of 5.8 or less after an ammonium chloride load, has a urine**

osmolality of 600 mOsm/kg or higher in response to water deprivation, has a GFR that exceeds 35 mL/min, and has minimal protein in the urine, the patient may be considered for a retentive diversion.

Key Points

- Complications that occur with ureterointestinal anastomoses include leakage, stricture, reflux in those anastomoses that were performed to prevent reflux, and pyelonephritis.
- The incidence of urinary intestinal leak is markedly reduced by the use of stents.
- Antirefluxing techniques have a higher incidence of stricture than refluxing anastomotic techniques.
- The Wallace anastomosis has the lowest complication rate of any ureterointestinal anastomotic technique.
- In the long term, there is significant and progressive deterioration in renal function in the majority of patients independent of the type of urinary diversion caused. This deterioration is caused by a lack of ureteral motility, infection, stones, or less commonly a stricture at the anastomotic site.

Urinary Diversion

This section deals with specific types of conduit urinary diversions. Fundamentally, there are two types of conduits: (1) those using the small bowel, which includes the jejunum or ileum and (2) those in which a portion of large bowel is used. Conduits made of stomach have been described but are rarely indicated and may carry with them difficult problems of stomal maintenance. Their construction is not discussed here. Each type of conduit has specific indications and advantages, and for each there are specific complications. Some complications, however, are similar among all types. **The indications for a conduit are the need for urinary diversion: after a cystectomy; because of a diseased bladder; before transplantation in a patient who has a bladder that cannot adequately receive the transplant ureter; and for dysfunctional bladders that result in persistent bleeding, obstructed ureters, poor compliance with upper tract deterioration, and inadequate storage with total urinary incontinence.**

This section describes features that are unique to the construction of the conduit. The complications cited for each conduit also depend on the length of follow-up and the concomitant procedure performed. Orthotopic neobladder construction is discussed in a separate chapter.

Ileal Conduit

In the ileal conduit procedure, a portion of distal ileum is chosen. **It is the simplest type of conduit diversion to perform and is associated with the fewest intraoperative and immediate postoperative complications. It is not advisable to use ileum for a conduit in patients with a short bowel syndrome, in patients with inflammatory small bowel disease, and in those whose ileum has received extensive irradiation, often as a consequence of prior radiation therapy for a pelvic malignant neoplasm.**

Procedure

A segment 10 to 15 cm in length is selected 10 to 15 cm from the ileocecal valve. The cecum and ileal appendage (i.e., that portion of the distal ileum fixed to the retroperitoneum) are mobilized. The ileal mesentery is transilluminated, and a major arcade to the segment selected is identified. With a mosquito clamp, the mesentery immediately beneath the bowel is penetrated, and the bowel is encircled with a vessel loop. An area at the base of the mesentery that is to one side of the feeding vessel is selected, and a second vessel loop is placed through the mesentery. At this juncture, the peritoneum overlying both sides of the mesentery is incised from bowel vessel loop to the base of mesentery vessel loop. With mosquito clamps, the tissue is clamped, severed, and tied with 4-0 silk. A portion of mesentery 2 cm in length is cleared away from the bowel beneath the mesenteric incision. This procedure is repeated at the other end of the selected segment. The base of the mesentery should be as wide as possible and the mesenteric windows not excessive (in general about 5 cm in length) to prevent ischemia of the segment. Allen clamps are placed across the bowel in an angled fashion such that the antimesenteric portion is shorter than the mesenteric portion. (Some prefer to transect the bowel with an anastomotic stapler.) Thus, a triangular piece of bowel is removed and discarded.

The isolated ileal segment is placed caudad, and an ileoileostomy is performed as described earlier (Fig. 139.34). The mesenteric window of the ileoileostomy is closed with interrupted 3-0 silk sutures. The isolated segment is then flushed with copious amounts of saline until the irrigant is clear, at which point the ureters are brought out the retroperitoneum in the right lower quadrant. To accomplish this, the left ureter must be brought over the great vessels and posterior to the sigmoid mesentery to the rent in the posterior peritoneum.

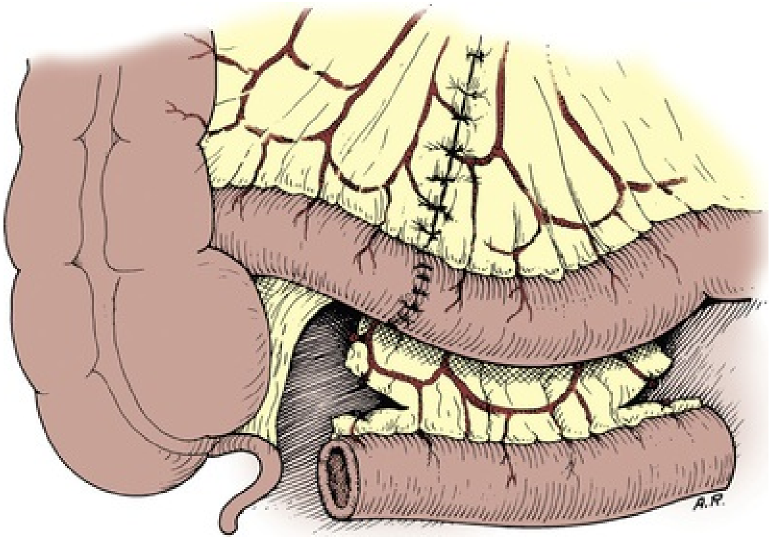

FIG. 139.34 The isolated segment of ileum is placed caudal to the ileoileostomy. An incision on the mesentery of the isolated segment 1 cm

from the bowel wall straightens the end. In general, this is not necessary unless the mesentery is excessively bulky.

The cecum is mobilized cephalad to identify the right ureter. The left ureter may be identified by incising the line of Toldt of the left descending colon (Fig. 139.35). This dissection allows anastomosis of the ileal segment as proximally as needed to the ureter. Indeed, the ileum may be anastomosed directly to the renal pelvis on both sides if necessary (see Fig. 139.35C). After a cystectomy, the ureters are identified caudad to the iliac vessels and may be conveniently traced cephalad similar to the previous description. The ureteroileal anastomoses are performed as described earlier. These anastomoses are stented.

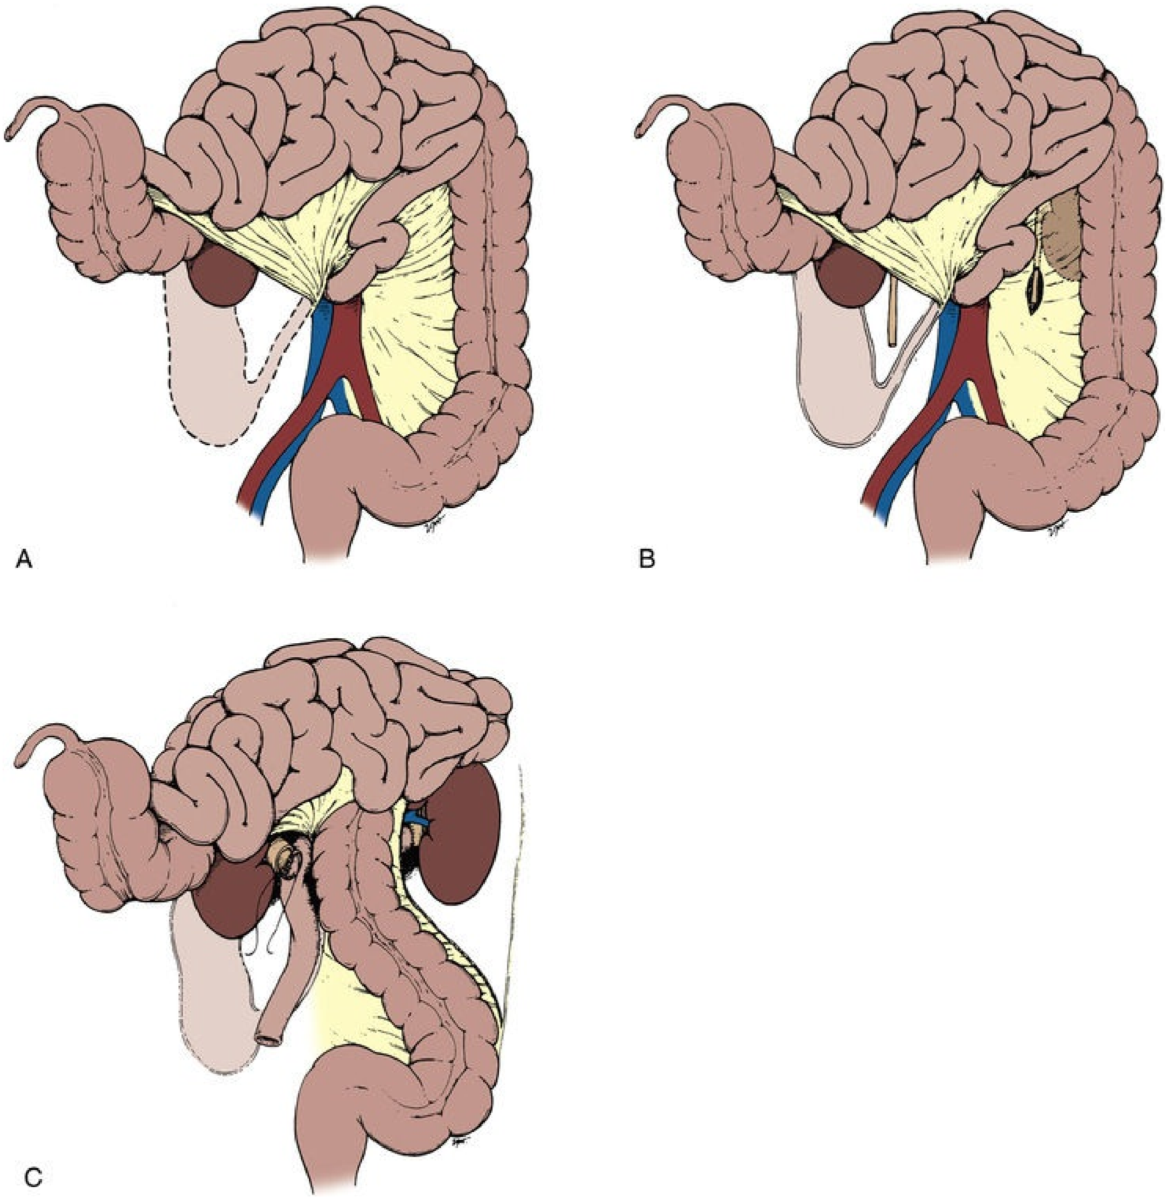

FIG. 139.35 (A) The cecum and root of the mesentery are incised. By blunt dissection, the cecum, ascending colon, and small bowel are mobilized cephalad. (B) The right and left ureters are identified. The left ureter is more easily identified by mobilizing the left colon. (C) The left colon is mobilized by incising the line of Toldt. This degree of mobilization allows anastomosis of the ileal segment to as proximal a position to the ureter as needed. This figure depicts a left renal pelvic and right ureterointestinal anastomosis.

A convenient method of introducing the stent through the loop to the opening in the bowel is illustrated in Fig. 139.36. The base of the conduit is fixed to the retroperitoneum in the right lower quadrant by suturing the posterior peritoneum to the conduit, thus effectively retroperitonealizing the ureterointestinal anastomosis. The stoma is made as described earlier. We prefer to suture the loop segment to the lateral peritoneal wall, thus obviating any chance of herniating small bowel lateral to the conduit. Many prefer to bring the segment directly to the anterior abdominal wall, however, thus allowing bowel to descend caudad on either side of the loop.

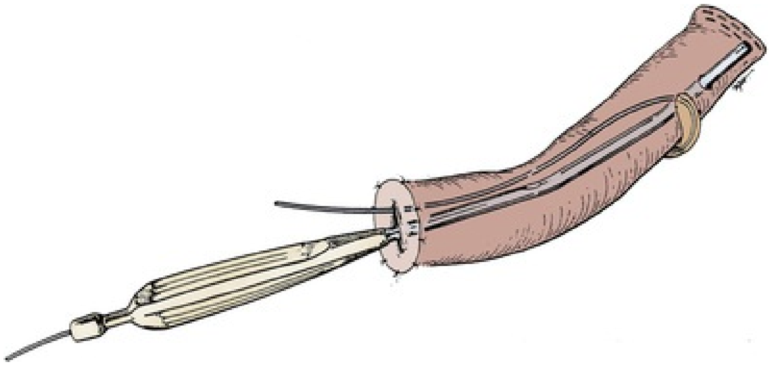

FIG. 139.36 The ureterointestinal anastomoses should be stented with soft Silastic stents. These stents may be conveniently introduced with a Yankauer suction instrument from which the tip has been removed. The suction instrument is introduced by way of the distal end of the segment to the desired location of the ureteral anastomosis. When one cuts down on the Yankauer tip, its end protrudes through the bowel at the desired site. The stent is threaded through the suction instrument, and the instrument is removed.

Robotic and laparoscopic surgical approaches have been described, with similar 90-day complication rates in the hands of experienced robotic surgeons (Ahmed et al., 2014).

Complications

Early and late postoperative complications are listed in Table 139.10. It is difficult to clearly ascribe these complications solely to construction of the conduit because many are reported in patients undergoing a cystectomy as well. These incidences in Table 139.10 are therefore expected to reflect the high end of the spectrum. **Bleeding may occur from either the stoma or the conduit itself. Approximately 10% of patients have stomal bleeding. In 4%, it originates from the loop beneath the fascia** (Delgado and Muecke, 1973). Bleeding that is extremely difficult to manage may be a result of cirrhosis and varices. In this situation, life-threatening bleeding from the conduit may occur. To stop the bleeding, portal decompression may be required. This may involve percutaneous transhepatic portal shunt or transhepatic angiography with embolization (Carrafiello et al., 2007; Lashley et al., 1997; Medina et al., 1998). **Complications not listed include hypertension, renal failure, decreased renal function, and death.** These complications in large part depend on the concomitant procedure performed, the length of follow-up, and the status of the kidneys before diversion. **During the long term (20 years), 7% of patients have renal failure requiring dialysis, and 60% show deterioration of the upper tracts** (Koch et al., 1992)**. Salvage cystectomy is associated with acceptable morbidity, although complication rates are higher than for other cystectomy series. Immediate salvage cystectomies (persistent disease after induction course of chemoradiation) have more cardiovascular/hematologic complications, and delayed salvage cystectomies (those with invasive recurrence after completion course of chemoradiation) have more tissue-healing complications** (Eswara et al., 2012).

TABLE 139.10

Complications: Ileal Conduit[a]

	EARLY	LATE
Urine leak	2% (9/356)	
Bowel leak		
Sepsis	3% (7/230)	3% (4/142)
Acute pyelonephritis	3% (21/700)	18% (133/726)
Wound infection	7% (17/230)	2% (4/178)
Wound dehiscence	3% (11/326)	
Gastrointestinal bleeding	2% (2/90)	
Abscess	2% (3/168)	
Prolonged ileus	6% (14/230)	
Conduit bleeding	2% (3/178)	10% (18/178)
Intestinal obstruction	3% (18/610)	5% (42/878)
Ureteral obstruction	2% (14/610)	6% (56/878)
Parastomal hernia		2% (9/454)
Stomal stenosis		3% (143/486)
Stone formation		7% (59/822)
Excessive conduit length		9% (26/276)
Metabolic acidosis		13% (27/206)
Conduit infarction		2% (2/90)
Volvulus		0.7% (2/268)

Conduit stenosis		3% (11/320)
Conduit-enteric fistula		<1%

[a] Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

Also, the complication rate is increased in patients in whom an intestinal segment is used who require renal transplantation (Nguyen et al., 1990).

One should be cautious in identifying duplex ureters. A failure to identify a second ureter on one side results in intraperitoneal urine leak and can cause excessive morbidity (Evans et al., 1994). The duplex ureters may be dealt with by implanting them separately if they are of sufficient caliber, or they may be spatulated, sewn together, and then implanted into the ileal conduit as a single unit (Fig. 139.37).

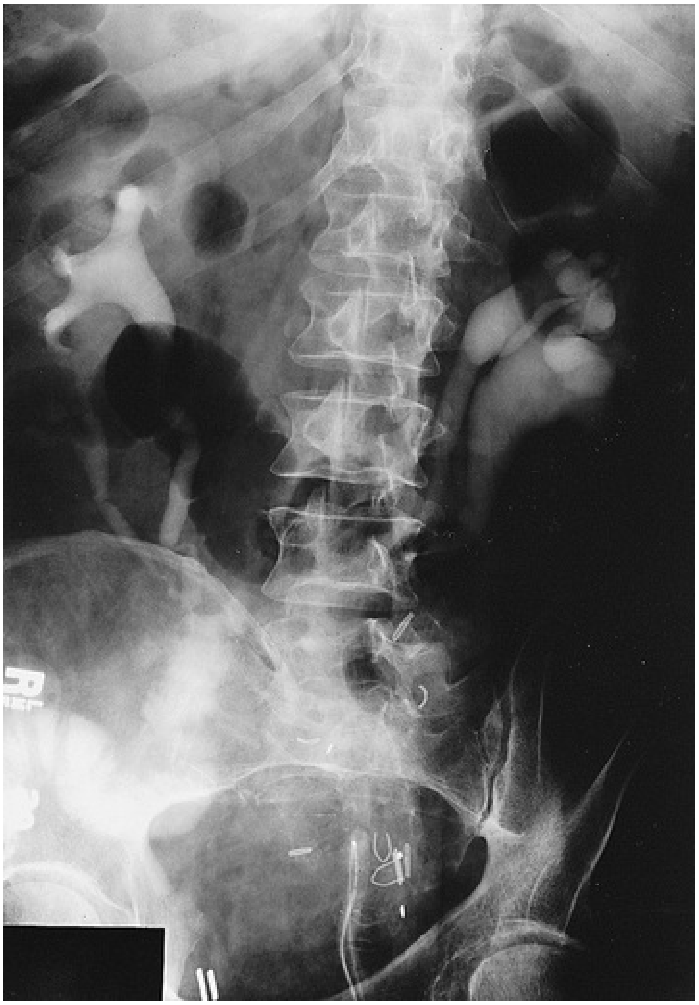

FIG. 139.37 Intravenous urogram 6 days postoperatively in a patient who had bilateral duplex ureters. The ureters on each side were spatulated,

sewn together, and anastomosed to the ileum.

Jejunal Conduit

The jejunum has the largest diameter of the small bowel and the longest mesentery. In general, jejunal conduits have not had a high rate of acceptance because of perceived electrolyte abnormalities. A more recent report of patients, most of whom were observed for more than 5 years, has shown that the bulk of electrolyte problems are minor; only about 4% in that series had severe hyponatremic metabolic acidosis. Renal calculi (12%), parastomal hernia (6%), and pyelonephritis (4%) constituted the majority of the remaining complications (Fontaine et al., 1997). The advantage of using the jejunum is that it avoids irradiated bowel and ureter. It is difficult to make a case for the jejunal conduit except in circumstances in which it is inadvisable to use either colon or ileum. However, this series does point out that when necessary, one can successfully use jejunum as a conduit. This might occur in patients who have extensive irradiation that involves the ileum, those with severe adhesions of the ileum and absence of the large bowel, and those who have an absent colon with inflammatory disease of the distal small bowel. **The contraindications to its use are severe bowel nutritional disorders and the presence of another acceptable segment.**

Procedure

The procedure is similar to that for an ileal conduit. A 10- to 15-cm segment of jejunum is isolated 15 to 25 cm from the ligament of Treitz as described for the ileal conduit. One should typically plan for the stoma to be in the left upper quadrant. The remainder of the technique is as described for the ileal conduit.

Complications

The early and long-term complications are similar to those listed for ileal conduit except that the electrolyte abnormality is a hyperkalemic, hyponatremic metabolic acidosis instead of the hyperchloremic metabolic acidosis of ileal diversion (Table 139.11). The treatment of jejunal syndrome consists of administration of sodium chloride and sodium bicarbonate. Thiazide diuretics may also be used and are helpful in allaying the hyperkalemia (Hasan et al., 1994).

TABLE 139.11

Complications: Jejunal Conduit[a]

	EARLY	LATE
Urine leak	14% (3/21)	
Wound dehiscence	5% (1/21)	
Acute pyelonephritis		10% (2/21)
Gastrointestinal bleeding	4% (1/27)	
Electrolyte abnormalities		27% (17/62)
Stomal stenosis		7% (2/27)
Bowel obstruction		7% (2/27)
Ureteral stricture		12% (5/41)
Enteric fistula	2% (4/140)	

[a] Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

Colon Conduit

Three types of colon conduits are commonly used: transverse, sigmoid, and ileocecal. Each has specific indications with advantages and disadvantages.

The transverse colon is used when one wants to be sure that the segment of conduit used has not been irradiated in individuals who have received extensive pelvic irradiation. It is also an excellent segment when an intestinal pyelostomy needs to be performed. The sigmoid conduit is a good choice in patients undergoing a pelvic exenteration who will have a colostomy. Thus no bowel anastomosis needs to be made. It also allows nonrefluxing submucosal reimplantation and provides for an easily placed left-sided stoma when that is desirable.

The use of sigmoid colon is contraindicated with disease of this segment or when the hypogastric arteries have been ligated and the rectum has been left in situ. The latter circumstance may result in sloughing of the rectum or its mucosa because its blood supply of necessity is interrupted. **It is also unwise to use this segment in individuals with extensive pelvic irradiation** because it has probably been included in the radiation fields.

An ileocecal conduit has the advantage of providing a long segment of ileum when long segments of ureter need replacement and the advantage of providing colon for the stoma. It is also used in situations in which free reflux of urine from the conduit to the upper tracts is thought to be undesirable. **Contraindications to the use of transverse, sigmoid, and ileocecal conduits include the presence of inflammatory large bowel disease and severe chronic diarrhea.**

Procedure

Transverse Colon.

The segment may be isolated on the right or middle colic arteries, most commonly the latter (Fig. 139.38). The gastrocolic ligament is taken down, and the omentum is dissected from the portion of colon that is to be isolated. The splenic and hepatic flexures should be mobilized next. The proper length of segment is determined by taking into consideration the desired location of the stoma and the length of available ureters. In general, a length of 15 cm is sufficient. It is important not to isolate a segment that is too short and therefore incapable of reaching the retroperitoneum in such a position that a tension-free ureterocolonic anastomosis may be performed and retroperitonealized. The segment is isolated between bowel clamps, and a two-layer colocolostomy or stapled anastomosis is performed as outlined earlier. The segment is placed caudad to the anastomosis. If a colopyelostomy is to be performed, the segment should be placed cephalad to the bowel anastomosis. The isolated segment is irrigated with copious amounts of saline until the effluent is clear. The proximal end is closed with a running Connell suture of 3-0 chromic and a second layer of Lembert sutures of 3-0 silk. The ureterocolic anastomoses are then performed (see earlier), and the end is anchored to the retroperitoneum close to the midline. The stoma is usually placed in the right upper quadrant but may be placed anywhere in the abdomen if indicated.

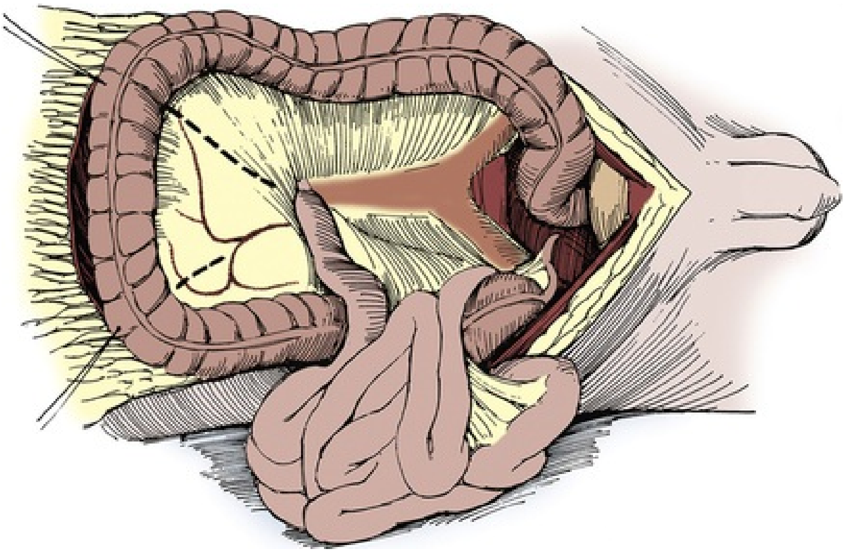

FIG. 139.38 Transverse colon conduit may be based on right colic or middle colic arteries *(depicted).* (From Hinman F Jr. *Atlas of urologic surgery*. Philadelphia, PA: Saunders; 1989.)

Sigmoid Colon.

The sigmoid colon is mobilized by incising its peritoneal attachments and the line of Toldt along the descending colon. The segment is isolated on the sigmoid vessels and placed lateral to the sigmoid colon (Fig. 139.39). The anastomosis of the sigmoid colon and ureterocolic anastomosis are as described for the transverse colon.

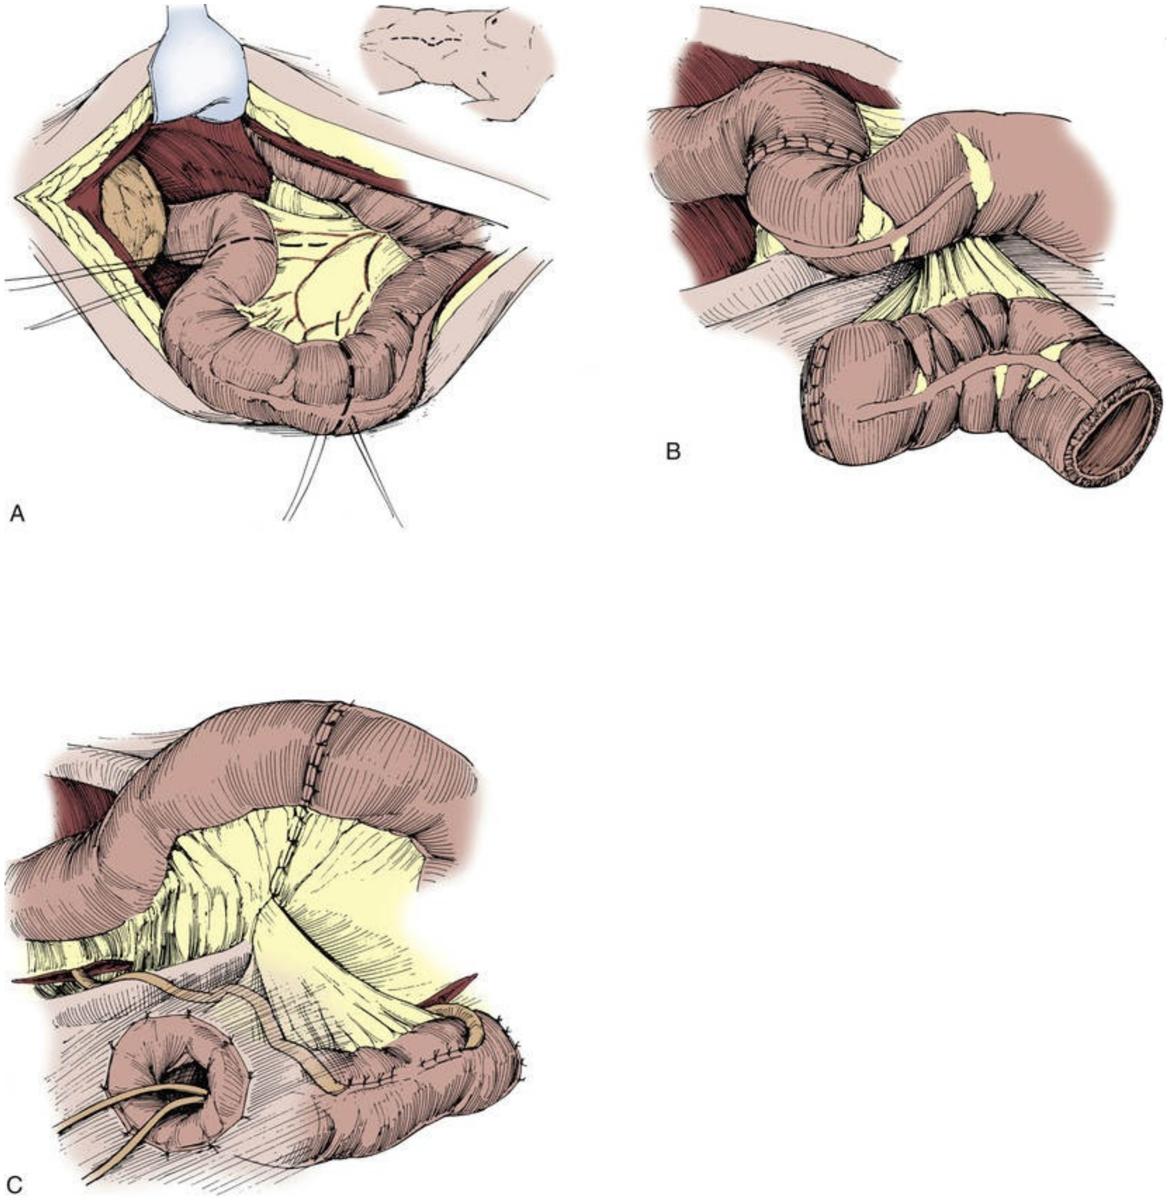

FIG. 139.39 (A) The sigmoid colon is freed of any peritoneal attachments. (B) The segment is isolated and placed laterally. Bowel continuity is restored, and the mesenteric window is closed. (C) The ureters are anastomosed to the colon and stented. (From Hinman F Jr. *Atlas of urologic surgery*. Philadelphia, PA: Saunders; 1989.)

Ileocecal Conduit.

The ileocecal conduit is based on the terminal branches of the superior mesenteric artery (i.e., ileocecal artery). The segment is placed caudad, and an ileum–ascending colon anastomosis is performed as described earlier. The stoma is placed in the right lower quadrant. The ileocecal valve may be reinforced to ensure prevention of reflux. This is described earlier (see Fig. 139.31). For the ureterointestinal anastomoses, also see the earlier description.

Complications

Early and late complications after a transverse colon, sigmoid, or ileocecal conduit are listed in Tables 139.12 to 139.14 (Beckley et al., 1982; Ravi et al., 1994; Schmidt et al., 1985). As is true for the small bowel, complications not listed including death, renal failure, and renal deterioration depend on the concomitant procedure performed and the length of follow-up. It is interesting to note that early reports suggested a lower incidence of renal deterioration with colon conduits, but some recent series suggest that the incidence of these complications is about the same. However, there continue to be proponents of the colon conduit because in the long term the apparent incidence of pyelonephritis is 7.6% and of preservation of the upper tracts is 78% (Stein et al., 1996b).

TABLE 139.12

Complications: Transverse Colon Conduit[a]

	EARLY	LATE
Urine leak	8% (11/137)	8% (2/25)
Acute pyelonephritis		11% (8/75)
Wound infection	5% (5/92)	
Wound dehiscence	7% (8/109)	
Abscess		5% (3/62)
Prolonged ileus	6% (2/30)	
Ureteral stricture	6% (5/84)	17% (37/215)
Bowel obstruction	3% (1/30)	2% (2/109)
Parastomal hernia		4% (5/114)
Stones		11% (11/98)
Enterocutaneous fistula		2% (1/62)
Stomal stenosis		2% (1/62)
Stomal prolapse		11% (6/56)
Metabolic acidosis		12% (3/26)

[a] Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

TABLE 139.13

Complications: Sigmoid Conduit[a]

	EARLY	LATE
Urine leak	1% (1/70)	
Wound infection	1% (1/70)	
Wound dehiscence	1% (1/70)	
Acute pyelonephritis		7% (5/70)
Bowel obstruction		6% (4/70)
Ureteral stricture		9% (6/70)
Stones		4% (3/70)
Parastomal hernia		3% (2/70)
Stomal stenosis		3% (2/70)

[a] Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

TABLE 139.14

Complications: Ileocecal Conduit[a]

	EARLY	LATE
Urine leak	6% (9/147)	
Bowel leak	3% (5/147)	
Gastrointestinal bleeding	1% (1/147)	
Wound dehiscence	7% (11/147)	
Acute pyelonephritis		14% (20/147)
Bowel obstruction	3% (5/147)	10% (14/147)
Stomal prolapse		16% (24/147)
Parastomal hernia		5% (7/147)
Stomal stenosis		2% (3/147)
Stones		5% (8/147)
Fecal fistula		2% (3/147)

[a] Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

Complications of the ileocecal conduit in one reported series occurred in 21% of patients (Matsuura et al., 1991). In this series, complications of the ileal conduit were compared with those of the ileocecal conduit, and there appeared to be no difference in the frequency of early and late postoperative complications.

Early complications included urinary leakage, bowel obstruction, fecal leakage, acute renal failure, fulminant hepatitis, pneumonia, gastrointestinal bleeding, hemorrhage, perforation of ileum, heart failure, and wound dehiscence. Late complications included stomal prolapse, acute pyelonephritis, bowel obstruction, urinary stones, parastomal hernia, incisional hernia, stomal stenosis, and fecal leakage. There was no difference in the incidence of deterioration of the upper tracts with either form of diversion. Of some note is that at high pressures, a large portion of the ileocecal conduits experienced reflux. At low pressures, however, there was minimal or no reflux. Whenever a portion of colon is used for a conduit, chronic diarrhea may be a consequence.

Ileal Vesicostomy

An ileal vesicostomy uses spatulated ileum and a generous transverse cystotomy to decompress the bladder and to allow an appliance to be used on the abdomen. This procedure is particularly well suited to spinal cord injury patients or those with significant neurologic disease. The concept is that patients with a neurogenic bladder have an easier job of caring for themselves with an abdominal stoma. Patients who are particularly good candidates are those with significant detrusor–external sphincter dyssynergia. Those who have detrusor hyperreflexia, particularly women, may have an increased incidence of incontinence. Complications of the procedure include urethral incontinence requiring closure of the urethra in 20% of patients, stomal stenosis, and bladder and renal calculi.

The procedure is performed by spatulating an ileal segment and performing a generous transverse cystotomy. The spatulated ileum is sutured to the bladder with absorbable suture, and the distal segment is brought to the abdominal wall by fashioning a rosebud stoma. This results theoretically in a low-pressure reservoir. Its appeal is that if indicated at a later date, the patient's anatomy can be converted back to normal (Mutchnik et al., 1997; Atan et al., 1999).

Management Common to All Conduits

All anastomoses are stented with Silastic stents. A convenient method for introducing the stents through the conduit and into the ureter is illustrated in Fig. 139.36. They are removed individually on the fourth to sixth postoperative days. If there is no increase in drainage, the Jackson-Pratt closed-suction drain is removed. **All conduits are retroperitonealized,** with the ureterointestinal anastomosis being placed in the retroperitoneum. This may be accomplished by suturing the posterior peritoneum to the serosa of the conduit above the ureterointestinal anastomosis. A drain may then be laid into the retroperitoneum. We prefer to drain the ureterointestinal anastomosis with a Jackson-Pratt or Blake closed-suction drain laid in the retroperitoneum 3 to 4 cm away from the anastomosis. The peritoneal cavity should not be drained.

Key Points

- Salvage cystectomy is associated with acceptable morbidity, although complication rates are higher.
- The ileal conduit is the simplest type of conduit diversion to perform and is associated with the fewest intraoperative and immediate postoperative complications.
- The transverse colon is the least likely segment of colon to be exposed to radiation in individuals who have received extensive pelvic irradiation.
- The sigmoid conduit is a good choice in patients undergoing a pelvic exenteration who will have a colostomy as no bowel anastomosis is required.

Metabolic and Neurochemical Problems of Urinary Intestinal Diversion

Problems that result from interposition of intestine in the urinary tract may be conveniently divided into three areas for the purposes of discussion: metabolic, neuromechanical, and technical-surgical. Metabolic complications are the result of altered solute reabsorption by the intestine of the urine that it contains. Neuromechanical aspects involve configuration of the gut, which affects storage volume and contraction of the intestine that may lead to difficulties in storage. Finally, technical-surgical complications involve aspects of the procedure that result in surgical morbidity; these have been discussed after each section on the technical aspects of urinary intestinal diversion. The following is a discussion of metabolic and neuromechanical problems.

Metabolic Complications

Metabolic complications include electrolyte abnormalities, altered sensorium, abnormal drug metabolism, osteomalacia, growth retardation, persistent and recurrent infections, formation of renal and reservoir calculi, problems ensuing from removal of portions of the gut from the intestinal tract, and development of urothelial or intestinal cancer. Many of these complications are a consequence of altered solute absorption across the intestinal segment. **Factors that influence the amount of solute and type of absorption are the segment of bowel used, the surface area of the bowel, the amount of time the urine is exposed to the bowel, the concentration of solutes in the urine, the renal function, and the pH of the fluid.**

Electrolyte Abnormalities

Serum electrolyte complications and the type of electrolyte abnormalities that occur are different, depending on the segment of bowel used. If stomach is used, hypochloremic metabolic alkalosis may occur. If jejunum is the segment used, hyponatremia, hyperkalemia, and metabolic acidosis occur. If the ileum or colon is used, hyperchloremic metabolic acidosis ensues. Other electrolyte abnormalities that have been described include hypokalemia, hypomagnesemia, hypocalcemia, hyperammonemia, and elevated blood urea nitrogen and creatinine. Specific abnormalities for each segment of intestine are detailed in the following sections and are summarized in Table 139.15.

TABLE 139.15

Syndromes of Electrolyte Disturbances in Patients in Whom Bowel Is Interposed in the Urinary Tract

---

		BLOOD		
SEGMENT	**SYNDROME**	**Na^+**	**K^+**	**Cl^-**
Stomach	Severe metabolic alkalosis	—	↓	↓
Jejunum	Hyperkalemic, hypochloremic metabolic acidosis	↓	↑	↓
Ileum/colon	Hyperchloremic metabolic acidosis	—	↓	↑

When stomach is used, hypochloremic, hypokalemic metabolic alkalosis may ensue. In general, this is not a significant problem unless the patient has concomitant renal failure, in which case there is a significant impairment of bicarbonate excretion or the patient is significantly dehydrated (Kurzrock et al., 1998). The metabolic alkalosis on occasion can be severe and life-threatening (syndrome of severe metabolic alkalosis). This syndrome has been reported in patients with normal renal function. **When it is fully manifested, lethargy, respiratory insufficiency, seizures, and ventricular arrhythmias may occur** (Castellan et al., 2012Gosalbez et al., 1993). These symptoms are usually preceded by vomiting resulting in dehydration. A pronounced hypochloremic, hypokalemic metabolic alkalosis ensues. Patients are usually successfully treated with an H_2 blocker to reduce proton secretion by the gastric segment and rehydration. In life-threatening circumstances, arginine hydrochloride infusion has been used to rapidly restore acid-base balance. On occasion, when H_2 blockers are ineffective, the proton pump blocker omeprazole has been successfully used. Rarely, omeprazole is ineffective, and if the life-threatening metabolic alkalosis persists, the gastric segment must be removed (Castellan et al., 2012).

The role of the serum concentration of gastrin appears pivotal in the syndrome. In the severe cases that have been reported, there is typically an elevated serum gastrin level. **Serum gastrin levels are significantly correlated with systemic bicarbonate concentration in gastrocystoplasty patients;** the greater the gastrin level, the more severe the metabolic alkalosis (Tanrikut and McDougal, 2004). When volume depletion, hypochloremia, and hypokalemia result from vomiting in those who normally have elevated circulating gastrin levels and a persisting long-standing metabolic alkalosis, the patient is at greater risk for development of the syndrome of severe metabolic alkalosis and manifestation of the symptoms outlined earlier. Thus, persistent loss of protons from the gastric-augmented bladder with net addition of bicarbonate to the systemic circulation, alteration of normal homeostatic mechanisms for acute changes in acid-base balance, and impaired ability of even a normal kidney to excrete bicarbonate in the face of hypochloremia, hypokalemia, and increased circulating aldosterone levels (because of the dehydration) create a vicious circle in which normal homeostatic mechanisms are circumvented. Indeed, elevated aldosterone levels have been reported in this syndrome (Gosalbez et al., 1993). Hypokalemia, hypochloremia, and increased aldosterone levels impair the kidney's ability to excrete excess bicarbonate. These perturbations coupled with a continued addition of bicarbonate from the gastric segment produce the extreme electrolyte abnormalities noted in the patients described. In view of the **sigmoid correlation of serum bicarbonate to gastrin levels in patients with gastric segments in the urinary tract, patients at greatest risk for development of the syndrome of severe metabolic alkalosis are those whose serum gastrin concentrations exceed 120 ng/L because on this portion of the**

curve, small additional increments in gastrin concentration result in large increases in serum bicarbonate (Fig. 139.40). On the other hand, patients with serum gastrin concentrations below 100 ng/L can have significant increases in gastrin levels with little change in serum bicarbonate. **Failure to properly empty the diversion with overdistention of the gastric segment would be expected to increase the serum gastrin level because stretch is a stimulus for gastrin release. For those who have either an elevated resting gastrin level in excess of 120 ng/L or impaired renal function, both patient and physician should be made aware of the consequences of dehydration and distention of the segment.**

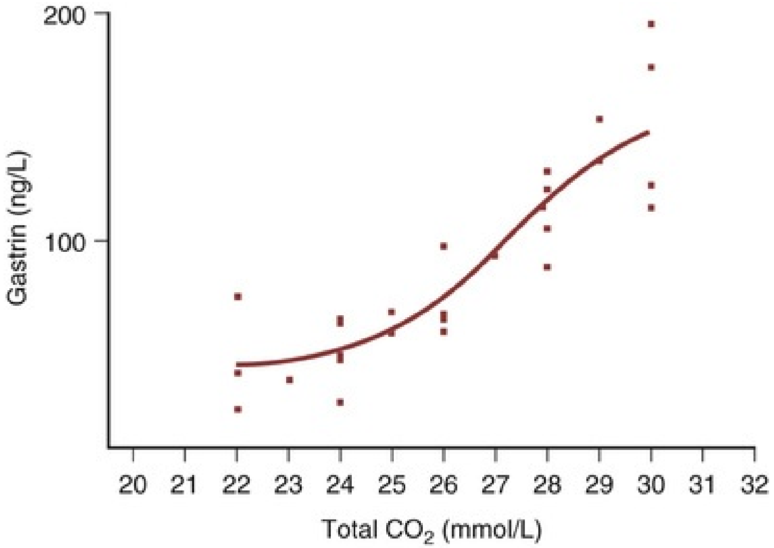

FIG. 139.40 Sigmoid relationship of serum gastrin level to serum bicarbonate. Notice that over the physiologic range of normal gastrin levels, 10 to 120 ng/L, there is little change in serum bicarbonate. However, at levels of serum gastrin in excess of 120 ng/L, small changes in serum gastrin levels result in large changes in serum bicarbonate.

Electrolyte disorders that occur when jejunum is used for urinary intestinal diversion, particularly when proximal jejunum is used, **include hyponatremia, hypochloremia, hyperkalemia, azotemia, and acidosis** (see Table 139.15). These disorders result from an increased secretion of sodium and chloride with an increased reabsorption of potassium and hydrogen ions. This excessive loss of sodium chloride carries with it water, and thus the patient becomes dehydrated. The dehydration results in hypovolemia, which increases renin secretion and thereby aldosterone production (Golimbu and Morales, 1975). Aldosterone production may also be stimulated by hyperkalemia. The high levels of renin-aldosterone facilitate sodium reabsorption by the kidney and potassium loss, which produce a urine low in sodium content and high in potassium. This, when presented to the jejunum, results in a favorable concentration gradient for loss of sodium by the jejunum and increased reabsorption of potassium, thus perpetuating the abnormalities.

These electrolyte abnormalities result in lethargy, nausea, vomiting, dehydration, muscle weakness, and elevated temperature. If the abnormalities are allowed to persist, the patient may become moribund and finally die. **This syndrome may be exacerbated by administration of hyperalimentation solutions.** The mechanism by which hyperalimentation solutions exacerbate this syndrome in patients with jejunal intestine interposed in the urinary tract is unclear (Bonnheim et al., 1984). **The severity of the syndrome depends on the location of the segment of jejunum that is used. The more proximal the segment, the more likely the syndrome is to develop.** Its incidence varies from a low of 25% (Klein et al., 1986) to the majority of patients demonstrating significant abnormalities. Severe abnormalities may occur in as few as 4% when short segments are used (Fontaine et al., 1997). Treatment of the disorder is rehydration with sodium chloride and correction of the acidosis with sodium bicarbonate. Provided that renal function is normal, the hyperkalemia is corrected by renal secretion. On occasion, a diuretic may be helpful to correct the hyperkalemia. After restoration of normal electrolyte balance, long-term therapy involves oral supplements with sodium chloride. A thiazide diuretic has also been useful in selected patients to control hyperkalemia in the long term (Hasan et al., 1994).

The electrolyte abnormality that occurs with the ileum and colon is hyperchloremic metabolic acidosis (see Table 139.10). This acidosis occurs to some degree in most patients who have ileum or colon interposed in the urinary tract but is usually of a minor degree. Its clinical significance when it is of a minor degree is unclear. Hyperchloremic acidosis has been reported with a frequency of 68% of patients (19 of 28 patients; 10 of the 19 cases were severe enough to require treatment) with ileal conduits (Castro and Ram, 1970). In another study, 70% of patients with ileal conduits observed for 4 years or longer had a decreased serum bicarbonate concentration (Malek et al., 1971). A more recent study places the incidence at about 25% (Nieuwenhuijzen et al., 2008) with about 4% requiring hospitalization for correction (Studer et al., 2006). Severe electrolyte disturbances occur to a much lesser degree. It has been reported to be a major problem in 18% of patients (8 of 45) with intestinal cystoplasties (Whitmore and Gittes, 1983), in 10% of patients (17 of 178) with ileal conduits (Schmidt et al., 1973), and in 80% of patients (112 of 141) with ureterosigmoidostomies (Ferris and Odel, 1950).

In continent diversions involving either ileum and cecum or cecum alone, most patients have an elevated serum chloride and depressed serum bicarbonate (Ashken, 1987; McDougal and Koch, 1989). Sixty-five percent of patients with Mainz pouches require alkali therapy to maintain a normal acid-base balance (Thüroff et al., 1986). Early reports of patients with continent diversions made of ileum note a much lower incidence of electrolyte problems, in the range of 10% to 15% (see Table 139.8) (Allen et al., 1985; Boyd et al., 1989). **Symptoms in those in whom the syndrome is severe include easy fatigability, anorexia, weight loss, polydipsia, and lethargy.** Those with ureterosigmoidostomies also have an exacerbation of diarrhea.

These electrolyte abnormalities, if significant and allowed to persist, result in major metabolic abnormalities, to be discussed later. In and of themselves, however, they may be lethal because severe electrolyte abnormalities have contributed to death of patients (Heidler et al., 1979).

The mechanism of hyperchloremic metabolic acidosis is a result of the ionized transport of ammonium. Ammonium substitutes for sodium in the Na^+-H^+ antiport. The exchange of the weak acid NH_4 for a proton is coupled with the exchange of bicarbonate for chloride. **Thus ammonium chloride is absorbed across the lumen into the blood in exchange for carbonic acid (i.e., CO_2 and water).** Ammonium may also gain entry to the blood from bowel lumen through potassium channels (McDougal et al., 1995).

The treatment of hyperchloremic metabolic acidosis involves administration of alkalizing agents or blockers of chloride transport. Alkalinization with oral sodium bicarbonate is effective in restoring normal acid-base balance. Oral administration of bicarbonate may not be tolerated particularly well, however, because it can produce considerable intestinal gas. An effective alternative is sodium citrate and citric acid solution (Bicitra or Shohl's solution) used together; however, many patients do not care for the taste. Potassium citrate, sodium citrate, and citric acid solution (Polycitra) may be used instead if excessive sodium administration is a problem because of cardiac or renal disease and if potassium supplementation is desirable or at least not harmful. In patients in whom persistent hyperchloremic metabolic acidosis occurs and in whom excessive sodium loads are undesirable, chlorpromazine or nicotinic acid may be used to limit the degree of the acidosis. These agents used alone do not correct the acidosis in humans, but they limit its development and thus reduce the need for alkalinizing agents. Chlorpromazine and nicotinic acid inhibit cyclic adenosine monophosphate and thereby impede chloride transport. Chlorpromazine may be given at a dose of 25 mg three times a day. On occasion, as much as 50 mg three times a day may be necessary, but at such doses, side effects are not uncommon. Chlorpromazine should be used with care in adults because there are many untoward side effects including tardive dyskinesia. Nicotinic acid may be given at a dose of 400 mg three or four times a day. The drug should not be used in patients with peptic ulcer disease or significant hepatic insufficiency. Side effects that may be observed include exacerbation of liver dysfunction, exacerbation of peptic ulcer disease, headache, and double vision. Flushing and dermatitis are not uncommon and generally disappear as the patient becomes adapted to the drug.

Hypokalemia and total-body depletion of potassium may occur in patients with urinary intestinal diversion. This is more common in patients with ureterosigmoidostomies than it is in patients who have other types of urinary intestinal diversion (Geist and Ansell, 1961). In one study, patients with ureterocolonic diversions had a 30% reduction in total body potassium, whereas those with ileal conduits had, as a group, no significant alteration in total body potassium; individually, however, some had as much as a 14% reduction in total body potassium (Williams et al., 1967). Patients with continent diversions have also been noted to have a decrease in total body potassium. The patients most susceptible to total body potassium depletion are those with long-standing uncorrected metabolic acidosis (Stein et al., 1998). **The potassium depletion is probably caused by renal potassium wasting as a consequence of renal damage, osmotic diuresis, and gut loss through intestinal secretion.** The last-mentioned (probably quantitatively) plays a relatively minor role. Indeed, it has been shown that ileal segments exposed to high concentrations of potassium in the urine reabsorb some of the potassium, whereas colon is less likely to do so (Koch et al., 1990). Thus **those with ileum interposed in the urinary tract likely blunt the potassium loss by the kidney, whereas those with colon do not, which explains why patients with ureterosigmoidostomies and ureterocolonic diversions are more likely to have total body potassium depletion.** When the depletion is severe, the patient may develop a flaccid paralysis. **In treating these patients, one must remember that if the hypokalemia is associated with severe hyperchloremic metabolic acidosis,**

treatment must involve both replacement of potassium and correction of the acidosis with bicarbonate. If the acidosis is corrected without attention to potassium replacement, severe hypokalemia may occur, marked flaccid paralysis may develop, and significant morbidity may ensue (Koff, 1975).

Because the bowel transports solutes and because its membrane is not particularly watertight, osmolality generally re-equilibrates across the bowel wall. Thus **attempts to deprive a patient of water and determine osmolality as a reflection of renal function are inappropriate because the bowel alters the osmotic content. The bowel also makes the contents more alkaline, and therefore it is impossible to determine the ability of the kidney to acidify simply by measuring urinary pH in patients with urinary intestinal diversion. Finally, because urea and creatinine are reabsorbed by both the ileum and the colon, serum concentrations of urea and creatinine do not necessarily accurately reflect renal function** (Koch and McDougal, 1985; McDougal and Koch, 1986).

Histologic alterations of the intestine may occur over time when urine is chronically exposed to the mucosa. Villous atrophy and the formation of pseudocrypts may occur, particularly in the ileum. These changes are patchy because there is normal ileal mucosa interspersed between these abnormalities. Submucosal inflammatory infiltrates may also be observed. There appear to be fewer changes in the colonic mucosa during the long term. In the colon, a decrease in the size of goblet cells has been described. In time, some transport processes may be altered, with some solutes less actively transported, whereas other processes of solute transport remain active (Philipson et al., 1983). **The ability to establish a hyperchloremic metabolic acidosis, however, appears to be retained by most segments of ileum and colon over time.** In an experimental study, chronic exposure of intestine to urine resulted in a decreased number of transporters, but those that remained were perfectly functional (Grocela and McDougal, 1999).

Altered Sensorium

Alteration of the sensorium may occur as a consequence of magnesium deficiency, drug intoxication, or abnormalities in ammonia metabolism. Patients who develop magnesium deficiency do so either secondary to nutritional depletion or in relation to magnesium wasting by the kidney in much the same way that calcium wasting occurs (see later). Alterations in the sensorium have also occurred because of diabetic hyperglycemia; however, this is not a consequence of the intestinal diversion. In such patients, reabsorption of urinary glucose can result in hyperglycemia without demonstrable glucosuria (Onwubalili, 1982). Perhaps the more common cause of an altered sensorium is altered ammonia metabolism. **Ammoniagenic coma in patients with urinary intestinal diversion has been reported in those with cirrhosis (Silberman, 1958), those with altered liver function without underlying chronic liver disease** (McDermott, 1957), and those with normal hepatic function as determined by serum enzyme activities (Kaufman, 1984; Mounger and Branson, 1972; Perez-Fidalgo et al., 2007). The syndrome is most commonly associated with decreased liver function, however, and even in patients in whom normal liver function has been reported, the crude methods by which it was assessed in these reports have made it impossible to confirm the absence of subtle alterations in liver function. The syndrome is most commonly found in patients with ureterosigmoidostomies but has been reported in those with ileal conduits as well (McDermott, 1957).

The treatment of ammoniagenic coma involves draining the urinary intestinal diversion, either with a rectal tube in patients with ureterosigmoidostomy or with a Foley catheter in those with a continent diversion so that the urine does not remain exposed to the intestine for extended periods. **Neomycin is administered orally to reduce the ammonia load from the enteric tract, and protein consumption is curtailed,** thus limiting the nitrogen load to the patient until serum ammonium levels have returned to normal. In severe circumstances, arginine glutamate, 50 g in 1000 mL of 5% dextrose in water, may be given intravenously. This complexes the ammonia by providing substrate for the formation of glutamine (Silberman, 1958). Lactulose may be given orally or by rectum (Edwards, 1984). This complexes the ammonia in the gut and prevents its absorption. Consult the hospital pharmacist for dosages and schedules of these therapies.

Abnormal Drug Absorption

Drug intoxication has been reported in patients with urinary intestinal diversion. **Drugs more likely to be problematic are those absorbed by the gastrointestinal tract and excreted unchanged by the kidney.** Thus the excreted drug is re-exposed to the intestinal segment, which then reabsorbs it, and toxic serum levels develop. This has been reported with phenytoin (Savarirayan and Dixey, 1969) and with certain antibiotics that are excreted unchanged. Although chemotherapy is usually well tolerated by patients with conduits, methotrexate toxicity has been documented in a patient with an ileal conduit (Bowyer and Davies, 1987).

A more recent study suggests that in patients with normal renal function, both those with and those without continent diversions tolerate chemotherapy well. The authors studied 23 patients with continent diversions and 19 with ileal conduits who received cisplatin, methotrexate, and vinblastine. The authors concluded that there was no difference in toxicity in patients without diversions, those with ileal conduits, and those with continent diversions. Indeed, the patients with continent diversions did not have a Foley catheter placed during the chemotherapy infusion. However, if one looks carefully at the data, it appears that there is in fact an increased toxicity in the continent diversion group, although it did not achieve statistical significance (Srinivas et al., 1998). In patients receiving antimetabolites, it is prudent to carefully monitor the patient for toxic products that are excreted in the urine and capable of intestinal absorption, lest lethal toxic serum levels develop. Moreover, **in patients with continent diversions who are receiving chemotherapy, consideration should be given to draining the pouch while the toxic drugs are being administered.**

Osteomalacia

Osteomalacia or renal rickets occurs when mineralized bone is reduced and the osteoid component becomes excessive. Osteomalacia has been reported in patients with colocystoplasty (Hossain, 1970), ileal ureters (Salahudeen et al., 1984), colon and ileal conduits, and, most commonly, ureterosigmoidostomies (Harrison, 1958). **The cause of osteomalacia may be multifactorial but commonly involves acidosis.** With persistent acidosis, the excess protons are buffered by the bone with release of bone calcium. This results in increased serum calcium and therefore calcium excretion by the kidney to maintain hemostasis. Support for the theory that chronic acidosis is causative in osteomalacia comes from those patients in whom correction of the acidosis results in remineralization of the bone (Richards et al., 1972; Siklos et al., 1980). It has also been shown, however, that major alterations in serum bicarbonate are not necessary for the development of the syndrome (Koch and McDougal, 1988; McDougal et al., 1988). Moreover, some patients with osteomalacia secondary to urinary intestinal diversion do not have bone demineralization corrected with restoration of normal acid-base balance. **These patients have been found to manifest vitamin D resistance that is independent of the acidosis.** It is likely that this resistance is of renal origin. Resistance can be overcome by supplying

1α-hydroxycholecalciferol, a vitamin D metabolite that is much more potent than vitamin D_2. When this substrate is provided in excess amount, remineralization of bone occurs (Perry et al., 1977). Also, it has been shown that reabsorption of urinary solutes may play a role in increasing calcium excretion by the kidney. Sulfate filtered by the kidney inhibits calcium reabsorption and results in both calcium and magnesium loss by the kidney. Thus if the gut increases its sulfate reabsorption and requires the kidney to increase sulfate excretion, this results in hypercalciuria and hypermagnesuria (McDougal and Koch, 1989). Finally, there is some evidence to indicate that the calcium-to-parathormone ratio is altered, suggesting that a resistance to parathormones develops during the long term (Tanrikut and McDougal, 2004). **Osteomalacia in urinary intestinal diversion may be caused by persistent acidosis, vitamin D resistance, and excessive calcium loss by the kidney. It appears that the degree to which each of these contributes to the syndrome may vary from patient to patient.**

It is clear that a number of metabolic problems have been obviated when meticulous attention is paid to correction of the abnormalities prospectively. If a base deficit of more than 2.5 mEq/L is corrected, some investigators have found no evidence of bone mineral density abnormalities (Stein et al., 1998). Indeed, the type of diversion does not seem to make a difference when the acidosis is taken into account and corrected (Kawakita et al., 1996). Others suggest that there is no difference in continent diversions and ileal conduits (Campanello et al., 1996); however, in such selected series, the distribution of acidosis across both groups is typically identical. It is clear that if the groups are large enough and not preselected, there is an increased incidence of acidosis in continent diversion patients. Indeed, if patients are followed long enough, some will develop bone mineral density abnormalities, particularly those who are acidotic over the long term (Incel et al., 2006). The take-home message is that if one pays meticulous attention to correction of the acidosis, bone mineral density abnormalities will probably not become a problem.

In general, patients who develop osteomalacia report lethargy; joint pain, especially in the weight-bearing joints; and proximal myopathy. Analysis of serum chemistries reveals that the calcium concentration is either low or normal. The alkaline phosphatase level is elevated, and the phosphate level is low or normal (Harrison, 1958). The treatment as indicated earlier involves correction of the acidosis and dietary supplementation of calcium. If this does not result in remineralization of the bone, the active form of vitamin D may be administered. If this is not successful, the more active metabolite of vitamin D_3, 1αhydroxycholecalciferol, should be administered.

Growth and Development

Considerable evidence suggests that urinary intestinal diversion has a detrimental effect on growth and development. In a study of 93 myelodysplasia patients observed for 17 to 23 years, significant aberrations in growth were noted when morphometric parameters were analyzed. Anthropometric measurements in those with urinary intestinal diversion showed a decrease in linear growth in all indices measured, with a statistically significant decrease in biacromial span and elbow-hand length (Koch et al., 1992).

Patients with long-term urinary diversions are more susceptible to fractures and to complications after orthopedic procedures. When myelodysplastic patients with ileal conduits were compared with a similar group of patients who retained their bladder and were on intermittent catheterization, the patients with an ileal conduit had an increased number of fractures, and malunions and nonunions after orthopedic procedures (Koch et al., 1992). It was found that more patients with urinary intestinal diversion fell below the tenth percentile than did patients who were treated with intermittent catheterization. There was, in fact, no difference in height and weight between the two groups studied (Koch et al., 1992; McDougal, 1992).

There is also experimental evidence for impaired linear growth in urinary intestinal diversion. Rats with unilateral ureterosigmoidostomies observed long term demonstrated significantly decreased femoral bone length compared with nondiverted controls (Koch and McDougal, 1988). Thus it appears clear that, although obvious alterations in growth and development do not occur in the majority of patients, when carefully studied, patients who have urinary intestinal diversions constructed in childhood and who maintain these diversions for more than 10 years have significant changes in linear growth.

Infection

An increased incidence of bacteriuria, bacteremia, and septic episodes occurs in patients with bowel interposition. A significant number of patients with intestinal cystoplasty develop pyelonephritis, and 13% have septic and major infectious complications (Küss et al., 1970). The episodes are more frequent after colocystoplasty than ileocystoplasty (Küss et al., 1970). In a contemporary series, 4% of patients were admitted to a hospital for sepsis

(Studer et al., 2006). Acute pyelonephritis occurs in 10% to 17% of patients with colon and ileal conduits (Hagen-Cook and Althausen, 1979; Schmidt et al., 1973; Schwarz and Jeffs, 1975). Approximately 4% of patients (8 of 178) with ileal conduits die of sepsis (Schmidt et al., 1973).

Patients with conduits have a high incidence of bacteriuria. **Approximately three-fourths of ileal conduit urine specimens contain bacteria** (Elder et al., 1979; Guinan et al., 1972; Middleton and Hendren, 1976). It is clear that some patients are merely colonized at the distal end of the conduit because the incidence of positive cultures can be markedly diminished by culture of the proximal portion of the loop by a double-catheter technique (Smith, 1972). Many of these patients, however, show no untoward effects and seem to do well with chronic bacteriuria. **Deterioration of the upper tracts is more likely when the culture becomes dominant for *Proteus* or *Pseudomonas.* Thus patients with relatively pure cultures of *Proteus* or *Pseudomonas* should be treated, whereas those with mixed cultures may, in general, be observed, provided they are not symptomatic. Patients with continent diversions also have a significant incidence of bacteriuria and septic episodes** (McDougal, 1986). Indeed, two-thirds of patients with Kock continent diversions have positive cultures (Kock, 1987). The reasons for the increased incidence of bacteriuria and sepsis are unclear, but it is likely that the intestine is incapable of inhibiting bacterial proliferation, in contrast with the urothelium. Thus intestine that normally lives symbiotically with bacteria when interposed in the urinary tract serves as a source for ascending infection and septic complications. Moreover, the intestine may make the urine less bacteriostatic and thereby promote the growth of bacteria. Distention of the intestinal segment may aid in translocation of bacteria across the intestine and into the blood. Studies have shown some changes in intestinal mucosal immunologic bacterial defense mechanisms; however, for the most part they seem to be preserved (Wullt et al., 2004).

Stones

One of the consequences of persistent infection is the development of magnesium ammonium phosphate stones. Indeed, **the great majority of stones formed in patients with urinary intestinal diversions are composed of calcium, magnesium, and ammonium phosphate. Those most susceptible to development of renal calculi are patients who have hyperchloremic metabolic acidosis, preexisting pyelonephritis, and urinary tract infection with a urea-splitting organism** (Dretler, 1973). The incidence of renal stones is

3% to 4% in patients with colon conduits (Althausen et al., 1978; Hagen-Cook and Althausen, 1979) and 10% to 12% in those with ileal conduits (Schmidt et al., 1973). In those with continent cecal reservoirs, there is a 20% incidence of calculi within the reservoir (Ashken, 1987). The stones may be a result of persistent infection with alkalinization of the urine, persistent hypercalciuria for reasons described earlier, and alterations of urinary excretion products by the intestine. A major cause of calculus formation in conduits and pouches is a foreign body such as a staple or nonabsorbable suture, on which concretions form. In intestinal reservoirs, alterations in bowel mucus production may also serve as a nidus for stone formation. Finally, alterations in intestinal mucosa, particularly in the presence of infection or obstruction, may serve as a nidus or, more important, may interfere with emptying and thereby exacerbate infection and stone formation (N'Dow et al., 2004).

Intestinal Motility, Short Bowel, and Nutritional Problems

Many nutritional problems may occur from the loss of significant intestinal absorptive surface resulting from removal of substantial portions of the gut for construction of a urinary intestinal diversion. **In patients with a significant loss of ileum, vitamin B_{12} malabsorption has been reported and results in anemia and neurologic abnormalities.** Vitamin B_{12} deficiency has been shown to occur in 10 of 41 patients who received preoperative radiotherapy before radical cystectomy and ileal ureterostomy (Kinn and Lantz, 1984), and 21% of children who have undergone ileocystoplasty have low serum levels of vitamin B_{12} (Rosenbaum et al., 2008). **Loss of significant portions of ileum also results in malabsorption of bile salts.** Because the ileum is the major site of bile salt reabsorption, the lack of reabsorption allows bile salts entry into the colon, which causes mucosal irritation and diarrhea. Also, loss of the ileum results in the loss of the “ileal break.” The ileal break is a mechanism whereby gut motility is reduced when lipids come in contact with the ileal mucosa so that increased absorption can occur. With the loss of ileum, the lipid does not result in decreased motility and is presented unmetabolized to the colon, which may cause fatty diarrhea.

It has been difficult to demonstrate untoward effects of low serum vitamin B_{12} levels in these patients. The liver stores enough vitamin B_{12} to supply the body's requirement for 3 to 5 years without oral intake. Thus pathologic problems would not be expected to manifest themselves for many years and have rarely been reported. Moreover, low serum levels of vitamin B_{12} do not necessarily correlate with metabolic deficiency. To assess whether or not there is a metabolic impact, it is necessary to measure serum levels of homocysteine and/or methylmalonic acid. Because vitamin B_{12} serves as a coenzyme in the metabolic pathways of homocysteine and methylmalonic acid, their measurement is a sensitive indicator of whether the low vitamin B_{12} level is significant. These measurements have not been done in this group of patients, and thus it is unclear at this time as to the importance of vitamin B_{12} measurements in these patients. Many physicians, however, empirically give parenteral vitamin B_{12} as a precaution to patients who have had intestinal diversions of ileum in place for more than 5 to 7 years.

Loss of the ileocecal valve may have a number of untoward effects. Because of the loss of the valve, reflux of large concentrations of bacteria into the ileum may occur, resulting in small intestinal bacterial overgrowth. This may result in nutritional abnormalities that involve interference with fatty acid reabsorption and bile salt interaction. With the lack of absorption of fats and bile salts, these are presented to the colon and result in diarrhea. Moreover, reflux of bacteria into the small bowel may result in bile salt deficiency. Also, the lack of fat absorption may result in deficiencies of the fat-soluble vitamin A, osteomalacia caused by lack of vitamin D, and complexing of calcium with the fats to form soaps, thus preventing its absorption. The ileocecal valve also serves as a break, and an intact valve prolongs transit time of the small bowel and enhances absorption. Thus its loss may contribute to nutritional abnormalities. Some have advocated reconstruction of the valve mechanism between ileum and colon when the ileocecal segment is used for reconstruction.

Loss of a significant portion of jejunum may result in malabsorption of fat, calcium, and folic acid; however, significant portions of jejunum are rarely used for urologic reconstructive procedures. Loss of the colon may result in diarrhea because of lack of fluid and electrolyte absorption, loss of bicarbonate because of its increased secretion in the ileum and lack of reabsorption, and dehydration because of the loss of fluids.

Of concern when intestinal segments are used in urinary reconstruction is the effect removal of a segment of intestine from the alimentary tract might have on intrinsic bowel function. Indeed, removal of major segments from the alimentary tract may cause nocturnal bowel movements, fecal urgency, fecal incontinence, diarrhea, and nutritional deficiencies (Riddick et al., 2004). A study compared patients with ileal conduits with those who had segments used for clam cystoplasty and, not surprising, found that those with clam cystoplasty had a 40% incidence of significant bowel problems. It is known that there is an association between detrusor instability and irritable bowel, perhaps accounting for the incidence of untoward disorders of bowel function in this series (N'Dow et al., 1998). Thus, there is a need for heightened awareness of bowel dysfunction in patients with detrusor instability in whom bowel segments are to be used. A study of patients who had an ileocystoplasty noted that 7% had significant diarrhea (Blaivas et al., 2005). One should warn patients who will have major portions of the intestinal tract used in the reconstruction that bowel problems may ensue.

Cancer

The incidence of cancer development in patients with ureterosigmoidostomy varies between 6% and 29%, with a mean of 11% (Schipper and Decter, 1981; Stewart et al., 1982; Zabbo and Kay, 1986). In general, there is a 10- to 20-year delay before the cancer manifests. **On histologic examination, the tumors include adenocarcinoma, adenomatous polyps, sarcoma, and transitional cell carcinoma.** Case reports of tumors developing in patients with ileal conduits, colon conduits, bladder augmentations, rectal bladder, neobladders, and ileal ureters have been described (Austen and Kälble, 2004). Anaplastic carcinomas and adenomatous polyps have been reported in patients with ileal conduits. Adenocarcinoma has developed in patients with colon conduits; adenocarcinoma, undifferentiated carcinoma, sarcomas, and transitional cell carcinomas have developed in patients with bladder augmentations with both ileum and colon (Filmer, 1986).

The causative mechanism of development of the carcinoma is not understood. Whether the tumor arises from transitional epithelium or colonic epithelium is unclear. Because most of the tumors are adenocarcinomas, it has been assumed that the tumor arises from the intestinal epithelium. Adenocarcinomas have been shown to arise from transitional cell epithelium exposed to the fecal stream in experimental animals (Aaronson et al., 1987). Furthermore, studies show that the ureters in ureterosigmoidostomy patients have an exceedingly high incidence of dysplasia (Aaronson and Sinclair-Smith, 1984). Moreover, if the transitional epithelium is removed from the enteric tract, adenocarcinomas do not develop. **If the urothelium is left in contact with the intestinal mucosa, however, even though the diversion is defunctionalized and the area is not bathed in urine,**

adenocarcinoma may still develop. This is illustrated by a case report in which a patient who had a ureterosigmoidostomy that was defunctionalized with a conduit subsequently developed cancer 9 months later. The distal ureters at the sigmoid were left in situ. Twenty-two years later, the patient developed cancer at the site of the ureterointestinal anastomosis (Schipper and Decter, 1981). This suggests that **when ureterointestinal anastomoses are defunctionalized, they should be excised rather than merely ligated and left in situ.** Other evidence including cell staining techniques suggests that the colon is the primary organ of origin (Mundy, personal communication, 1991). Whether the urothelium or intestine is the primary site of origin, it seems likely that tumors can arise from both tissues.

The highest incidence of cancer occurs when the transitional epithelium is juxtaposed to the colonic epithelium and both are bathed by feces (Shands et al., 1989). Nitrosamines, known mutagens, are produced in rats with ureterosigmoidostomy (Cohen et al., 1987), but there appears, at least at this juncture, no convincing evidence to support a primary role for them in the genesis of the tumor. An abnormal pattern of colonic mucin secretion has been demonstrated in patients with ureterosigmoidostomy, but its significance is unclear (Iannoni et al., 1986). Induction of specific enzymes associated with carcinoma has also been demonstrated. Ornithine decarboxylase, an enzyme that has been found to be elevated in malignant colonic mucosa, is also elevated in experimental animals with vesicosigmoidostomy (Weber et al., 1988). The role of epidermal growth factor and other growth factors is currently being investigated. Evidence suggests that these may at least play a role in development, if not in induction. At this time, the cause of the genesis of cancer in urinary intestinal diversion is not known.

A recent analysis from Germany looked at 17,758 urinary diversions from 1970 to 2007 and noted 32 secondary malignancies. **Ureterosigmoidostomies (2.6%), cystoplasties (1.6%), and orthotopic (ileo)colonic neobladders (1.3%)** had the highest risk for malignancy. As a result, the authors recommended **regular endoscopic evaluation beginning 5 years postoperatively for these patients,** but not for patients with ileal neobladders (0.05% risk) and ileal conduits (0.02% risk), whose risk was significantly lower. The authors also recommended that patients with catheterizable ileocecal pouches (0.14% risk), should undergo evaluation in the presence of symptoms such as hydronephrosis, chronic urinary infection, and hematuria (Kälble et al., 2011).

Neuromechanical Aspects of Intestinal Segments

Both small bowel and colon contract to propel luminal contents in an aboral direction. The ability to propel luminal contents is a consequence of muscle activity and coordinated nerve activity. Both the small bowel and the colon have an outer longitudinal layer of muscle and an inner circular layer. There is also a muscularis mucosa, which is immediately beneath the mucosa and may extend into the villi. The outer and inner layers of muscle, however, play the major role in peristalsis. In the colon, the outer longitudinal layer of muscle condenses to form three taeniae coli. The bowel receives its parasympathetic innervation from the vagus nerve. It is also innervated by the sympathetic nervous system. The nerves lie between the circular and longitudinal layers of muscle. The enteral nervous system operates autonomously, and therefore one can denervate the intestine and not affect the coordinated contractions. These contractions are termed *activity fronts* and may be stimulated by feeding, or they may be inhibited by exposure of the lumen to various substances (e.g., lipid in the ileum decreases ileal motility). Two aspects of neuromechanical properties are particularly germane to urinary intestinal diversion: volume-pressure relationships and motor activity.

Volume-Pressure Considerations

The volume-pressure relationships depend on the configuration of the bowel. If one splits the bowel segment and turns it back on itself, the volume may be doubled if the ends are not closed (Fig. 139.41). In reconstruction of intestinal segments for the urinary tract, however, one must close the ends. Thus the limit of doubling the volume is never quite reached. Indeed, **the greater the ratio of length to diameter, the greater the volume change when the ends are closed. If the ends are closed when a ratio of diameter to length of 1 : 3.5 is reached, splitting the segment no longer increases the volume. By splitting most segments, one is, in fact, increasing the volume by about 50%. The goal in reconfiguring the bowel is to achieve a spherical storage vessel. This configuration has the most volume for the least surface area.** By increasing the volume, it has been suggested that pressure relationships within the confines of the intestine are reduced. This is based on Laplace's law, which states that for a sphere, the tension of its wall is proportional to the product of the radius and pressure. Thus theoretically, for a given wall tension, the greater the radius, the smaller the generated pressure. This is desirable in an attempt to prevent deterioration of the upper tracts or incontinence. **This relationship (Laplace's law), however, may not be accurately reflected for intestinal segments because they are not perfectly spherical, and the intestinal wall does not conform to Hooke's law,** which states that the force needed to extend or compress a spring by some distance is proportional to that distance. **Rather, the bowel demonstrates viscoelastic properties, which tend to distort the relationship between pressure applied at the wall and tension generated in it.** However, even though the mathematical modeling is complex, it seems desirable to attempt to construct as spheric a container as possible if one is attempting to make a reservoir.

FIG. 139.41 Effect of "detubularization." The bowel is split on its antimesenteric border and divided in two. When the two segments are placed together, the circumference is doubled, thus doubling the volume. Closing the ends of the cylinder requires a reduction in its length equal to the radius of the end. This limits the increase in volume that occurs by reconfiguration.

Over time, the volume capacity of segments increases. This occurs only if they are frequently filled. Their volume decreases with time if they are nonfunctional (Kock et al., 1978). Over time, it can be demonstrated that there is a marked accommodation in volume of pouches made from intestine. For ileal pouches, it has been shown that the capacity increases sevenfold after 1 year

(Berglund et al., 1987). As the reservoirs increase in volume, there is a significant increase in smooth muscle thickness of the bowel wall (Philipson et al., 1983).

Motor Activity

It has been suggested that splitting the bowel on its antimesenteric border discoordinates motor activity and thereby causes a lesser intraluminal pressure. Clearly, the ideal situation is to provide the patient with a spheric vessel that has few or ineffective contractions of its walls. It can be demonstrated in experimental animals that after **the bowel wall has been split on its antimesenteric border and reconfigured, acutely there is a marked interruption of coordinated activity fronts, which over a period of 3 months return to their normal coordinated state** (Concepcion et al., 1988). This has also been demonstrated clinically; initially after reconfiguration of the bowel (detubularization), coordinated activity fronts have been shown to decrease. During extended periods, however, many of the peristaltic waves (activity fronts) reappear and can be readily demonstrated (Fig. 139.42).

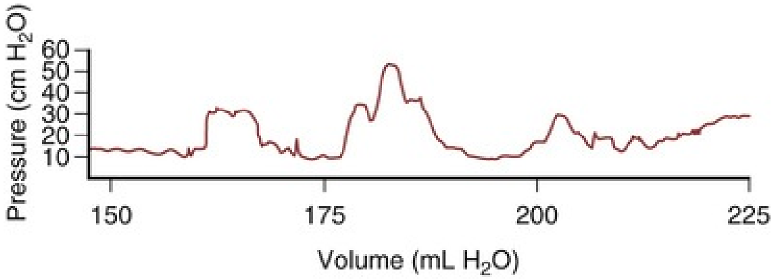

FIG. 139.42 Pressure waves recorded 1 year postoperatively in a patient with a continent diversion constructed from detubularized ileum and right colon. Note that the coordinated pressure waves are of magnitude and frequency similar to those found in a normal colonic or ileal segment.

The literature is contradictory with respect to the effect of detubularization on segments of ileum and colon used to construct storage vessels for continent diversions. Pressure within the lumen of bowel that has both ends closed may be increased by adding volume or reducing the size of the bowel through contractions of its wall. Because the bowel wall is freely permeable to water, the higher osmotic content of urine obligates movement of water into the bowel lumen. Most patients with continent diversions excrete 2 to 4 L/day (McDougal, 1986). In evaluating whether motor activity is the primary determinant of intravesical pressure, one must be cognizant of fluid volume changes. Also, as indicated earlier, early reports of detubularized segments would be expected to differ from later reports when coordinated activity fronts in these segments return.

These facts are often forgotten, and because pressure measurements are used to infer motor activity, rather than its direct measurement as reflected by changes in bowel wall tension, it is not difficult to understand why there are so many contradictions reported in the literature. Detubularization of ileal segments has been reported by some to decrease motor activity at 1 year compared with immediately postoperatively (Berglund et al., 1987), whereas others have noted increased motor activity at 1 year. Involuntary pressure waves occur in 25% of patients with Kock pouches. Maximum intravesical pressures average 41 cm H_2O in these pouches (Chen et al., 1989). Ileum has also been shown to have fewer activity fronts per unit of time than cecum (Berglund et al., 1986). Cecum has been observed to have the same number of activity fronts 1 year postoperatively, but the amplitude of the pressure waves has been observed to decrease over time (Hedlund et al., 1984). Maximum pressures in normal cecum have been shown to range from 18 to 100 cm H_2O (Jakobsen et al., 1987), whereas detubularized cecum has been shown to have pressures that range from 5 to 25 cm H_2O 1 year postoperatively (Hedlund et al., 1984). Others, comparing ileum to cecum, find no difference in pressure generated after 1 year (Hedlund et al., 1984). The Mainz pouch, which uses both ileum and cecum, has an average pressure at capacity of 39 cm H_2O with a maximum pressure of 63 cm H_2O (Thüroff et al., 1987). **Thus, reconfiguring bowel usually increases the volume, but its long-term effect on motor activity and wall tension is unclear at this time. It has been our observation that some patients with orthotopic bladders, after a number of years of spontaneous voiding, require intermittent catheterization. In these patients, the bowel segment has become flaccid, and the ability of the patient to generate intraluminal pressure by the Valsalva maneuver is limited.**

Key Points

- Limited segments of bowel should be used in patients who have an inability to acidify the urine to less than 5.8 and an inability to concentrate greater than 600 mOsm/kg or a GFR less than 35 mL/min.

- Metabolic complications of intestine interposed in the urinary tract include electrolyte abnormalities, altered sensorium, abnormal drug metabolism, osteomalacia, growth retardation, persistent and recurrent urinary tract infection, formation of calculi, short gut, and development of urothelial or intestinal cancers.
- The gastrocystoplasty patients most at risk for development of the syndrome of severe metabolic alkalosis are those with high resting levels of serum gastrin who overdistend their pouches and are dehydrated.
- The electrolyte abnormality that occurs with ileum and colon is a hyperchloremic metabolic acidosis.
- Patients receiving chemotherapy who have intestine interposed in the urinary tract have increased toxic effects of chemotherapeutic agents compared with patients with normal urinary tracts.

Summary

This chapter has addressed complications both independent of and dependent on the specific type of urinary intestinal diversion. Each unique type of diversion has its own set of individual complications. Moreover, the procedure preceding the urinary intestinal diversion also has a set of complications that must be added to those described earlier. It is clear that with current modalities of urinary intestinal diversion, long-term complications significantly contribute to mortality and morbidity. Many patients who have intestinal diversion after an extirpative procedure for cancer, however, die of the cancer rather than of these long-term complications. Those for whom a urinary intestinal diversion has been constructed for benign disease and those who are cured of cancer are most likely to experience long-term morbid complications. The knowledge of the frequency of these complications and the correct performance of preoperative preparation, surgical technique, and postoperative care, as outlined in this chapter, should provide the best chance for the least mortality and morbidity in patients undergoing urinary intestinal diversion.

Cutaneous Continent Urinary Diversion

Guarionex Joel DeCastro MD, MPH, James M. McKiernan MD, Mitchell C. Benson MD

General Considerations

Continent urinary diversion is a widely accepted form of urinary reconstruction after cystectomy. Orthotopic urethral anastomotic procedures and continent catheterizable stomal reservoirs have stood the test of time, and both procedures should be considered and offered to all appropriately selected patients. Given the metabolic consequences of continent urinary diversion, which are covered in separate chapters, patient selection is especially important. This chapter focuses on the most common continent cutaneous diversion surgeries associated with the highest success rates. Over the past 40 years the design of the reservoir has not substantially changed. Rather, an evolution has occurred in the techniques used to create antireflux and continence mechanisms to make these diversions more effective and reliable. In addition, attention will be given to the long-term quality-of-life outcomes of continent cutaneous reservoirs, as well as to the newer minimally invasive approaches used to create such reservoirs.

Despite the considerable enthusiasm for continent urinary diversion, those procedures requiring the use of external urinary collecting appliances remain more common. Although continent urinary diversion is certainly appropriate in selected patients, it is technically more challenging and is associated with higher short-term and long-term complication rates than procedures involving external collecting devices, thereby limiting the patient population that can undergo this type of diversion. However, the operating time associated with these more complex procedures has been significantly reduced by the widespread use of absorbable and metal staples in the construction of the reservoirs and limbs. In addition, as experience with continent urinary diversion has increased, complication rates have decreased. As a result, the use of continent diversions has also increased in some centers.

Patient Selection

Because the ability to self-catheterize is essential to the patient undergoing continent diversion, the patient must be assessed for the ability to care for himself or herself. The patient may be at greater ease with an enterostomal therapist to express concerns about forms of urinary diversion, so consultation with such a therapist may be extremely helpful. Certain patients may not be able to comprehend the strict flushing, irrigation, and catheterization regimens that must be followed after continent urinary diversion or may lack the motor skills to independently perform self-care. **Patients with multiple sclerosis, quadriplegic individuals, and very frail or mentally impaired patients will at some point in their lives require family or visiting nurses for basic care and are therefore viewed as poor candidates for any form of continent diversion.** Indeed, these patients may also require assistance with external appliances, but the degree of time and expertise required is much less burdensome on the care provider and the health care system. On the contrary, continent catheterizable diversion requires continuous attention and may limit patient and family options when determining long-term care needs.

Patient Preparation

All patients undergoing anticipated continent urinary diversion should be fully informed and prepared for the possibility that intraoperative findings may lead to the need to perform an ileal conduit diversion. Although this occurrence is rare, it always remains a possibility. Therefore the site for a potential external stoma should be selected with care before the operation. In general, the location must be free from fat creases in the standing and sitting positions, and it should not be close to the umbilicus or prior abdominal scars that may interfere with proper adherence of an external appliance. Here again, the aid of an enterostomal therapist is helpful. In general, the stoma should be brought through the right (or left) lower quadrant of the abdomen on a line extending from the umbilicus to the anterior superior iliac spine. The stoma should be as far lateral from the midline as possible, but the site selected should ensure that the bowel segment comprising the stoma traverses the rectus muscle. Failure to adhere to this rule increases the risk of parastomal hernias. The selected site for the stoma should be marked with an X scratched onto the anterior abdominal wall. Marking the stoma site with ink should be avoided because it may be washed away during the antiseptic preparation of the skin.

The surgeon undertaking continent urinary diversion should be familiar with more than one type of continent urinary diversion technique. Although it is uncommon to have to abandon a given bowel segment for the reservoir, it is not uncommon to have to modify the antireflux or continence mechanism. In these circumstances, it is essential that the surgeon be able to select an alternate form of continent diversion from what was originally intended.

Renal and hepatic function must be reviewed carefully in the patient selected for continent diversion (Mills and Studer, 1999). The reabsorption and recirculation of urinary constituents and other metabolites require that liver function be normal. Renal function should be determined preoperatively, and if borderline, creatinine clearance should be measured. A minimal level of at least 60 mL/min should be documented before the patient is deemed an appropriate candidate for continent diversion. In the case of unilateral or bilateral hydronephrosis, the upper urinary tract(s) should be decompressed with ureteral stenting or percutaneous nephrostomy, with subsequent reevaluation of renal function before consideration for a continent diversion.

Procedures that require the use of the colon should always be preceded by a colonoscopic assessment of the entire large intestine. Performing only a sigmoidoscopy for a procedure that will use only this segment of the large bowel is insufficient because disease proximal to the resected segment may leave the patient with short colon syndrome. The preoperative assessment of the colon is not mandatory but remains prudent if continent urinary diversion using small intestine is planned.

Most patients undergoing radical cystectomy can be admitted to the hospital on the day of surgery. In most institutions a mechanical bowel preparation is employed on the day before surgery, in addition to oral metronidazole (500 mg) the night before. This is still considered standard in any urinary diversion using large bowel. However, in addition to general surgery literature, several nonrandomized urologic studies have called into question the usefulness of preoperative bowel preparation for urinary diversion using small bowel (Large et al., 2012; Raynor et al., 2013). Intraoperative antibiotics (e.g., cefoxitin 1 to 2 g) should be administered within 1 hour of skin incision.

Cystectomy

Although robotic intracorporeal continent cutaneous urinary diversion has been reported by several authors, the majority of such procedures are today performed using an open approach. These require a midline incision, skirting the umbilicus to the side opposite the selected stoma site. The incision for a right colon pouch usually extends from the pubis to a point midway between the umbilicus and the xiphoid. The cranial extent of the incision is governed by the hepatic flexure, which must be divided to obtain sufficient colonic length and to allow for the right colon to easily fold on itself. On some occasions the incision will be extended to the xiphoid. The incision for procedures using only the ileum may only extend to just below the umbilicus, but the length of the incision should be tailored to the patient and will vary. The cystectomy procedure is covered elsewhere in this text, and only those points germane to continent diversion are covered here.

After abdominal exploration, the ureters are isolated, transected, and transposed to an appropriate place for subsequent diversion. The right retroperitoneum is first opened over the iliac artery to expose the right ureter. In the typical circumstance of conduit diversion, the right ureter is transected below the common iliac artery. For all continent diversions, both ureters are transected as low as possible and shortened to the appropriate length once the final anatomy has been determined. The sigmoid colon is freed from its lateral peritoneal attachments by incising along the line of Toldt. A wide tunnel is created by blunt finger dissection ventral to the aorta and common iliac arteries and caudal to the inferior mesenteric artery. This affords left ureteral access to the previously exposed right retroperitoneum. In cases of uroepithelial malignancy, it is prudent to evaluate the margin status of the most distal portion of both ureters using frozen-section analysis. In situations in which substantial ureteral length is removed to obtain negative surgical margins, extension of the afferent limb mechanism may be necessary to allow tension-free ureteral intestinal anastomoses.

All sutures used in the urinary tract should be absorbable. The individual surgeon's preference will dictate the caliber and type of suture material used. In carrying out bowel surgery for continent urinary diversions, stapling is the preferred method for division of the bowel segment as well as for reconstruction of bowel continuity. This technique shortens operative times greatly and affords safe and reliable bowel anastomosis. Suturing is not necessary with the exception of placing two silk Lembert sutures at the apex of side-to-side stapled bowel anastomoses to prevent tension on the staple line. To avoid stone formation on the stapled proximal bowel segments, oversewing the stapled end of the conduit with absorbable material isolates the metal staple line from urinary contact within the lumen.

To construct a nonappendiceal continent urinary diversion stoma, a skin button matching the diameter of the structure to be used in the diversion is resected. Cutaneous tissues are separated down to the level of the anterior rectus fascia, where a circle of similar diameter is excised from this fascia, or alternatively the fascia is incised in a cruciate fashion. In carrying out this maneuver, the surgeon must ensure the fascia and skin are properly aligned to avoid angulation. Rectus muscle fibers are separated bluntly, and an instrument is passed through the posterior fascia and peritoneum. For appendiceal stomas, we initially described and prefer to perform a Y-shaped cutaneous incision that allows for a YV-type plasty incision between the appendiceal limb and the skin (Fig. 140.1). This decreases the likelihood of subsequent stomal stenosis. Alternatively, the appendix lends itself to an umbilical stoma (Bissada, 1993; Gerharz et al., 1997). Favorable results with this appendiceal YV plasty technique to the umbilical site have been reported (Bissada, 1998).

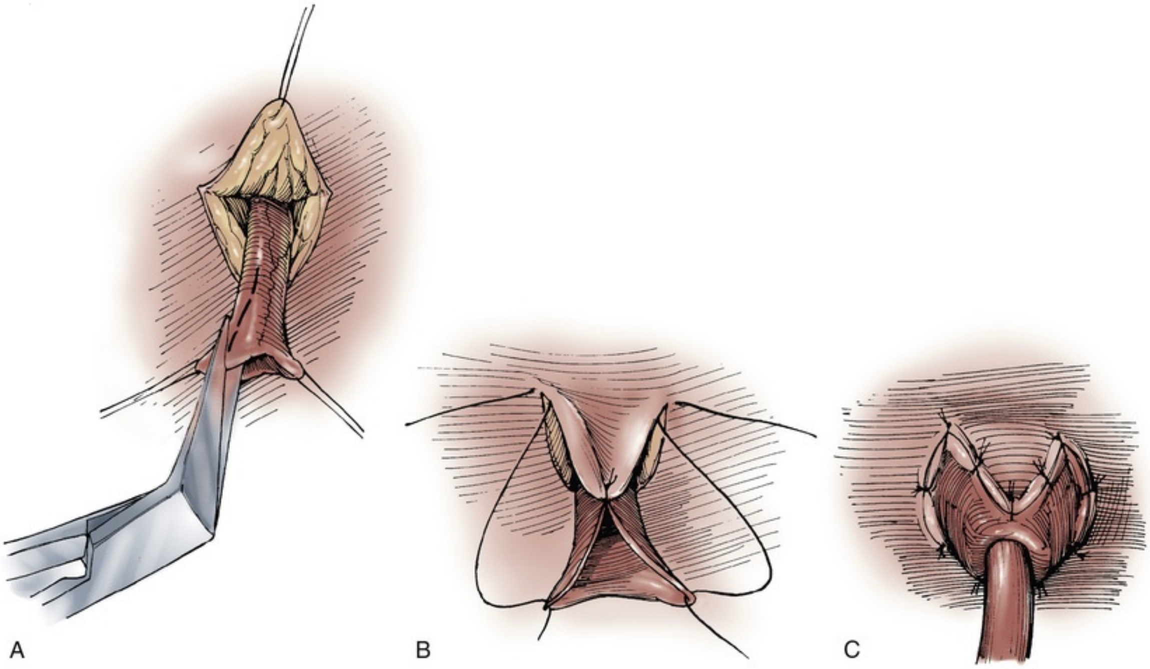

FIG. 140.1 (A to C) A V-flap is incised in the skin, and a similar-length

incision is made on the adjacent appendiceal surface. This is similar to the technique used to mature a cutaneous ureterostomy. For an appendiceal stoma, no eversion is required. (From Hinman F Jr: *Atlas of urologic surgery,* Philadelphia, 1989, Saunders.)

It is standard procedure to use long, single J–type 6- or 7-Fr diverting stents in all continent cutaneous urinary diversions. These stents drain urine externally, ensuring that urine is safely diverted beyond any anastomotic site during the early healing period. They can also be safely manipulated or exchanged if necessary. The distal end hole allows for the passage of a straight wire through the stent, which decreases the likelihood of anastomotic trauma at the time of stent removal.

We advocate the use of closed suction drains in all cases of urinary diversion. Soft silicone Jackson-Pratt closed suction drains are preferred because they have less potential for tissue damage or migration into pouches. The bulb suction should be opened before removal to prevent inadvertent creation of a hernia at the site.

Abdominal closure is performed according to the surgeon's preference. A single-layer closure with No. 2 nylon, Surgilene, or Prolene taken through all layers of fascia and muscle usually provides a rapid and secure abdominal closure in the majority of patients. In obese patients, those with tissues of poor quality, or nutritionally depleted patients, through-and-through stay sutures can also be used. Ureteral stents should always be brought through separate abdominal incisions, sutured to the anterior abdominal wall, and directed into separate drainage bags for monitoring of urine output. Even at this early stage it is important to ensure adequate drainage of the reservoir to prevent pouch rupture should the ureteral stents be displaced. In the case of limited pouch access such as with an appendiceal stoma, a large (approximately 28 Fr) Malecot tube should be placed directly into the reservoir and secured to the skin. The reservoir is sutured to the abdominal wall to prevent urine leakage into the peritoneal cavity when the tube is removed. This maneuver also helps to prevent migration and angulation of the reservoir, which could result in incontinence or catheterization difficulties.

Postoperative Care and Comments

Paralytic ileus is a common complication after urinary diversion procedures. Gastric decompression should be maintained until extubation. This can be achieved in the majority of patients by means of nasogastric intubation. However, a minority of patients may best be managed by formal gastrostomy decompression inserted intraoperatively. These individuals include those with multiple prior abdominal procedures in whom prolonged ileus is more likely. **If the patient is nutritionally depleted preoperatively, hyperalimentation has been suggested to be of value if initiated during the preoperative interval** (Askanazi et al., 1985; Hensle, 1983). A randomized controlled trial demonstrated that in nutritionally *noncompromised* patients, postoperative total parenteral nutrition was associated with increased infectious complications (Roth et al., 2013).

Ureteral stents are usually removed 1 to 2 weeks after surgery. Before manipulation, a urine sample from each stent should be sent for culture and sensitivity testing. Before stent removal, radiographs of the pouch may be obtained to ensure that the pouch is intact. Retrograde ureteral studies can be performed to ensure against ureteral anastomotic leakage. Each stent is injected with contrast agent in a search for extravasation; if none is seen, guide wires are advanced to each kidney, and the stents are removed. If there is any question of extravasation, stents can be advanced over the wires, positioned fluoroscopically, and left in situ for reevaluation after additional healing time. However, the use of ureteral retrograde studies before stent removal is by no means universal, and several retrospective studies have shown it to be of limited value (Pantuck et al., 1997; Touma et al., 2007).

Late malignancy has been reported in all bowel segments exposed to the urinary stream, whether there is a commingling with feces (Austen and Kalble, 2004; Filmer and Spencer, 1990; Shokeir et al., 1995). A study by Gitlin et al. (1999) suggests that the malignancy may develop from the urothelial component and not as a result of urine affecting intestinal mucosa. **As a result, urinary cytology should be performed for all patients undergoing a continent urinary diversion, whether the diversion was performed secondary to a urothelial malignancy. When the ureters are directed into the fecal stream, routine colonoscopy should also be performed. Latency periods as short as 5 years have been reported; therefore all patients**

developing gross or microscopic hematuria should be fully evaluated (Austen and Kalble, 2004; Golomb et al., 1989). If an anastomotic transitional cell cancer is discovered, the patient should be fully evaluated with upper tract imaging and ureteroscopy if possible. Antegrade ureteropyeloscopy can be employed if necessary. For an isolated anastomotic recurrence, distal ureterectomy and reimplantation may be appropriate. If nephroureterectomy is necessary, some patients may require removal of their continent diversion because of resulting renal insufficiency.

Continent Urinary Diversion

Continent, non-orthotopic urinary diversions can be divided into two major categories. First, the variations of ureterosigmoidostomy such as ileocecal sigmoidostomy, rectal bladder, and the sigmoid hemi-Kock operation with proximal colonic intussusception allow for excretion of urine by means of evacuation. Second is the large category of continent diversions requiring clean intermittent catheterization of the constructed pouch for urine drainage at standard intervals.

The concept of refashioning bowel so that it serves as a urinary reservoir rather than a conduit has become universally accepted. This concept is based on original pioneering observations by Goodwin et al. (1958) in the development of the cystoplasty augmentation procedure. The destruction of peristaltic integrity and refashioning of bowel has led to the development of many innovative urinary reservoirs constructed from bowel. Several procedures have been developed to prevent or reduce damage to the upper urinary tract from sepsis or increased pressure from ureteral reflux, and other techniques have evolved to achieve and maintain urinary continence.

Because numerous variants of continent urinary diversion are used worldwide, a complete review of all operative techniques is beyond the scope of this or any chapter. However, many of these procedures are simple modifications of parent operations. In this chapter we describe in detail each of these parent surgeries, as well as their major modifications. The fact that there are many continent urinary diversion procedures reveals an obvious corresponding fact: the “best” continent diversion has yet to be devised. There is no consensus that would indicate that one continent cutaneous diversion is superior to another, but it is becoming apparent that certain procedures are associated with lower early and late complication rates. Points of controversy include (1) which bowel segment is most appropriate for fashioning into a urinary reservoir, (2) the best techniques for achieving urinary continence, and (3) the best method for preventing urinary reflux into the upper tracts. There are now various continence mechanisms that appear reliable. In our experience, procedures using a right colon reservoir with some form of appendiceal continence mechanism are the fastest, most reliable, and easiest to perform.

Again, all continent diversions allow for substantial reabsorption of urinary constituents, which places an increased workload on the kidneys (Mills and

Studer, 1999). Patients with substantial renal impairment should not be considered for any of these procedures. The long-term sequelae of continent urinary diversion commonly involve significant renal damage. Although it has been suggested that the absence of reflux into the upper urinary tracts in catheterizable pouches may reduce the long-term impact of continent diversion procedures on renal function, long-term 15-year data are available, and in some instances, antireflux procedures are associated with a higher risk of obstruction caused by anastomotic stricture (Hohenfellner et al., 2002; Kristjansson et al., 1995). In addition to increased stricture rates, it is not clear whether anti-refluxing mechanisms actually result in improved preservation of the upper tracts (Pantuck et al., 2000; Rink et al., 2010).

The process of patient counseling that we employ refers to ileal conduit diversion as the gold standard against which the newer, more complex operations must be compared. The patient should be advised that continent diversion is, all other considerations being equal, associated with a longer hospital stay, as well as higher complication rates and greater potential for requiring reoperative surgery. Nieuwenhuijzen et al. (2008) reported on 281 consecutive radical cystectomies with urinary diversion using ileal conduit, orthotopic neobladder, or Indiana pouch. There were no significant differences in early complications among the three techniques. The incidence of late complications, including metabolic disturbances and ureteroileal anastomotic strictures, were similar between the two continent diversions but more frequent compared with patients with an ileal conduit. An extensive review from our institution has demonstrated no statistically significant difference in reoperations, mortality, or hospital stay in patients undergoing continent diversion versus conduit diversion by the same three surgeons over a 3-year period (Benson et al., 1992). Analysis of the two patient groups, on the other hand, showed that those selected for continent diversion were significantly younger and four times less likely to have significant concurrent illness. What this review suggests is that, with proper patient selection, continent diversion operations can be safely conducted with results similar to those for conduit diversion. To determine if continent diversion could be safely performed in selected elderly patients, Navon et al. (1995) compared the clinical course of 25 patients over the age of 75 years undergoing a modified Indiana reservoir with results in a cohort of 25 randomly selected patients younger than 75. The mean age of the first group was 78.5 years, and the mean age of the second was 59.3 years. The complication rates between the two groups were acceptably low and surprisingly similar. Navon et al. concluded that age alone should not be a contraindication to continent diversion and that the Indiana reservoir procedure can be successfully performed in elderly patients.

Rectal Bladder Urinary Diversion

Various innovative surgical techniques have been advocated for separating the fecal and urinary streams while still employing the principles of ureterosigmoidostomy. In general, these operations can be discussed together as rectal bladder urinary diversions. In each of these operations the ureters are transplanted into the rectal stump. The proximal sigmoid colon is managed by terminal sigmoid colostomy or, more commonly, by bringing the sigmoid to the perineum, thereby using the anal sphincter to achieve bowel and urinary control. Although these operations are commonly performed globally, they have never been well accepted in the United States. The principal reason is the potential for the calamitous complication of combined urinary and fecal incontinence, presumably occurring as a consequence of damage to the anal sphincter mechanism during the dissection processes (Culp, 1984).

If the urologist selects one of these procedures, the preoperative evaluation should include all of the caveats of ureterosigmoidostomy. Dilated ureters are not acceptable. Patients with extensive pelvic irradiation are not candidates, and neither are those with existing renal insufficiency. Anal sphincteric tone must be judged competent before these operations are selected. **Our preference has been to use a 400- to 500-mL thin mixture of oatmeal and water that the patient is asked to retain for 1 hour in the upright position** (Spirnak and Caldamone, 1986)**. Finally, colonoscopy should be carried out before the procedure to rule out preexisting colorectal disease, and surveillance must be ensured to monitor for subsequent development of colon cancer.** Procedures that separate the fecal and urinary streams but drain both through the rectal sphincter are not described here. Those seeking detailed descriptions of these procedures can find them in prior editions of this chapter. The following is a brief description of more modern surgical procedures that use the intact anal sphincter for urinary and fecal continence. However, the surgical techniques for these procedures are likewise not discussed in this edition.

Folded Rectosigmoid Bladder

A modification of the ureterointestinal anastomosis was described by a group from Mansoura, Egypt (El-Mekresh et al., 1997; Hafez et al., 1995). This procedure creates a folded rectosigmoid bladder with anastomosis of the ureters via serosa-lined tunnels rather than into the taenia coli. This procedure has the advantage of a larger sigmoid reservoir, as well as the prevention of reflux by creating the aforementioned serous-lined tunnel for the anastomosis. This reimplantation technique was first described by Abol-Enein and Ghoneim (1993) and appears to have a lower complication rate than direct taenial implantation (Hafez et al., 1995).

Postoperative Care and Comments.

Patients undergoing this procedure must be closely monitored for the development of hyperchloremic acidosis. This occurs in the majority of patients, and it is wise to initiate a bicarbonate replacement program after the operation. Because hypokalemia is also a feature of ureterosigmoidostomy, replacement of potassium along with bicarbonate may be achieved with oral potassium citrate. Routine nightly insertion of a rectal tube is advocated in the long-term care of the patient. However, many patients will reject this practice as uncomfortable and unappealing. Nighttime urinary drainage should be mandated for any patient who cannot maintain electrolyte homeostasis with oral medication. Bissada et al. (1995) reported that 30 of 61 patients were able to stay dry during the night without awakening. The other 31 required two or more awakenings to remain dry overnight. Hyperchloremic acidosis was reported in 4 of 61 noncompliant patients.

In 1997 El-Mekresh et al. (1997) reported on 64 patients (32 women, 20 men, and 12 children) who underwent their rectosigmoid bladder procedure from 1992 to 1995. Follow-up ranged from 6 to 36 months. Functional results were assessable in 57 patients: 1 died of a postoperative pulmonary embolism, and 6 died from their disease. All patients were continent during the day with 2 to 4 emptyings, and all but 4 remained dry at night with 0 to 2 emptyings. Four children experienced enuresis that responded to 25 mg of imipramine at bedtime. Upper urinary tract function was maintained or improved in 95% of patients. However, 6 renal units (5.3%) developed obstructive hydronephrosis secondary to ureterocolic anastomotic strictures. Two were remedied by antegrade dilation, one was repaired by open revision, and one nonfunctioning renal unit was removed. The fate of the remaining two units was not specified. No patient in this series developed postoperative metabolic acidosis. However, all patients were maintained on prophylactic oral alkalinization.

Obviously, all patients undergoing these procedures have exposure of the urinary tract to fecal flora. Some authors advocate chronic administration of an antibacterial agent to all such patients (Duckett and Gazak, 1983; Spirnak and Caldamone, 1986). Ureteral strictures require reoperative surgery and are experienced in 26% to 35% of patients over time (Duckett and Gazak, 1983; Williams et al., 1969).

Because of the concern for development of rectal cancer anywhere from 5 to 50 years (average, 21 years) after ureterosigmoidostomy (Ambrose, 1983), it is suggested that patients with long-term ureterosigmoidostomy undergo annual colonoscopy (Filmer and Spencer, 1990). Barium enemas are relatively contraindicated because reflux of this material into the kidneys (if the antireflux procedure fails) can be deleterious (Williams, 1984). Additional methods for colon carcinoma screening in this population are the evaluation of stool for blood and the attempted cytologic examination of the mixed urine and feces specimen (Filmer and Spencer, 1990).

Augmented Valved Rectum

Kock et al. (1988) developed the augmented valved rectum technique to be used in locales where stoma appliances were not readily available. This operation is similar to standard ureterosigmoidostomy except that a proximal intussusception of the sigmoid colon confines the urine to a smaller surface area, thus minimizing the problems of electrolyte imbalance. In addition, the rectum is patched with ileum to improve the urodynamic properties of the rectum as a urinary reservoir. Preoperative evaluation is similar to that used in ureterosigmoidostomy. The large bowel should be studied for preexisting disease, and anal sphincteric integrity must be tested before surgery.

Hemi-Kock and T Pouch Procedures with Valved Rectum

In his description of the augmented valved rectum procedure, Kock et al. (1988) described the use of a foreshortened hemi-Kock pouch to be used as a rectal patch when the ureters were too dilated to bring down between the leaves of the intussuscepted sigmoid. Skinner et al. (1989) then modified this procedure by using an entire hemi-Kock segment to augment the rectum after sigmoid intussusception.

After extensive experience with the Kock ileal reservoir, the group at the University of Southern California has attempted to improve on the intussuscepted Kock continence mechanism. The result has been the modification of the T pouch to serve as an ileal anal reservoir (Stein et al., 1999a). The technique consists of the construction of a hemi-Kock or T pouch employing doubly folded, marsupialized ileum and a proximal continence mechanism to prevent pouch-ureteral reflux. This pouch is then anastomosed to the rectum directly as a patch. Contact of urine with the proximal colon can be avoided by the intussusception of the sigmoid colon proximal to the anastomotic site (Fig. 140.2).

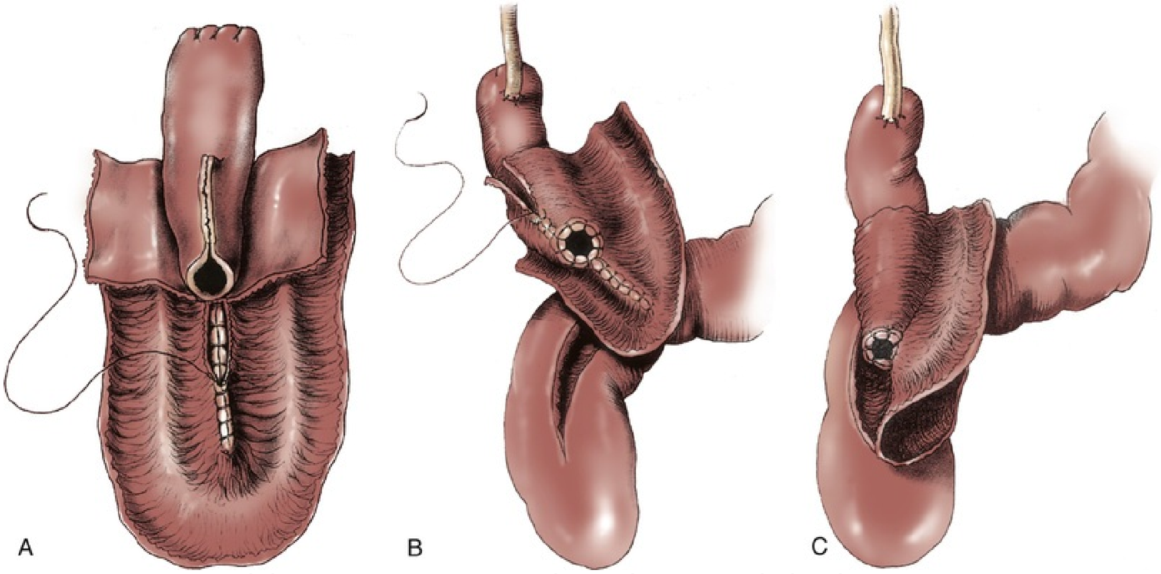

FIG. 140.2 (A) A 30-cm segment of ileum is selected, the first 10 cm for the T implant and the distal 20 cm for the patch. The 20-cm segment is folded into a U and opened as shown. The medial borders are closed with running absorbable sutures. (B) The ostium of the T is secured to the walls of the ileum with interrupted absorbable sutures. The wall of the ileum is closed over the T mechanism with a running absorbable suture. (C) The ureters are anastomosed to the top of the T in the usual end-to-side fashion. The T patch is then secured to the 15-cm proctotomy with a two-layer closure. (From Stein JP, Buscarini M, DeFilippo RE, Skinner DG: Application of the T pouch as an ileo-anal reservoir. *J Urol* 162:2052–2053, 1999b.)

Postoperative Care and Comments.

Postoperative management and complications associated with this operation are very similar to those that may be experienced after any procedure that directs the urinary stream into the rectum. Radiologic studies of the stents can be carried out after the seventh postoperative day. Before stent studies are conducted, a Gastrografin enema may be performed through the rectal tube to ensure that the region of ureterocolonic anastomosis is intact, with follow-up films to ensure prompt drainage of the upper urinary tracts into the rectosigmoid region. The rectal tube may be removed at this point, but some believe that it is advisable to have it reinserted for evening drainage over the forthcoming week. The patient is instructed to empty the colon at intervals of no more than every 2 hours, particularly in the early postoperative period.

When the rectal tube is removed, as in other situations when the urinary tract is diverted to the rectum, the patient must be closely monitored for the development of hyperchloremic acidosis. Because hypokalemic metabolic acidosis often occurs after ureterosigmoidostomy, bicarbonate replacement with oral potassium citrate should begin in the immediate postoperative setting. Long-term care should include nightly insertion of a rectal tube despite the uncomfortable and unappealing nature of the process. In addition, nighttime urinary drainage is necessary in patients who cannot maintain electrolyte homeostasis with oral medication.

The hemi-T procedure with valved rectum has one theoretic advantage over the valved rectum operation: because transitional ureteral epithelium is not in contact with colonic epithelium, there may be a reduced risk of development of colonic malignancy. As in the augmented valved rectum, the proximal colonic intussusception used in this procedure decreases the contact between urine and colonic epithelium, thereby potentially decreasing the risk of hyperchloremic acidosis. Nevertheless, attention should be paid to electrolyte levels after removal of stents and rectal tubes.

Skinner et al. reported on the results of the hemi-Kock procedure in 15 patients from 1987 to 1991 (Simoneau and Skinner, 1995). Four patients had prior bladder exstrophy and were converted to an ileoanal reservoir, and 11 patients underwent the procedure as a form of primary diversion after cystectomy. At the time of the report 10 patients were still alive and could be evaluated. Early postoperative complications occurred in 3 patients (20%): a colocutaneous fistula in 2 patients, urine leak in 1, and deep venous thrombosis in another. Late complications included partial small bowel obstruction in 4 patients (with 2 requiring surgery), urinary retention requiring surgery in 2 patients, and metabolic acidosis in 5 patients. Two of the 11 patients undergoing primary construction never achieved continence; both were older than 68 years. The authors summarized their experience by concluding that the operation is best suited for the younger exstrophy patient and that it is essential to avoid colonic redundancy distal to the reservoir. The use of the T pouch as an ileoanal reservoir has been reported in 1 former exstrophy patient (Stein et al., 1999a), with no reported postoperative complications.

Sigma-Rectum Pouch, Mainz II

A variation of ureterosigmoidostomy was described by Fisch and Hohenfellner in 1991 and updated in 1996 (Fisch et al., 1996). This operation, which they termed the *sigma-rectum* or the *Mainz II pouch*, creates a low-pressure rectosigmoid reservoir of increased capacity. They viewed the simplicity and reproducibility of the operation as two of its major advantages.

Postoperative Care and Comments.

The rectal tube is removed on the third to fifth postoperative day, and the ureteral stents are removed around the eighth day. On the 15th postoperative day the Mainz group performs an intravenous pyelogram to assess the upper tracts and the sigma-rectum pouch construction. Radiography of the pouch is performed on the 17th postoperative day.

The results of the Mainz II pouch were reported by Fisch et al. in 1996. From 1990 to 1993, 73 patients (59 adults and 14 children) underwent the Mainz II pouch procedure. Early complications were encountered in 5 of 73 patients (6.9%). These included single examples of a dislodged ureteral stent, pneumonia, pulmonary embolism, wound dehiscence, and ileus necessitating surgical intervention. There were 8 (11%) late complications that required surgery: ureteral stenosis occurred in 5 patients (6.9%); 1 patient with nephrolithiasis was treated with extracorporeal shockwave lithotripsy; 1 patient with rupture of the anterior suture line required temporary colostomy; and 1 patient experienced perianal bleeding after chemotherapy that required endoscopic coagulation. Six patients had pyelonephritis (8.2%) and were treated with antibiotics. Daytime and nighttime continence rates were reported as 94.5% and 98.6%, respectively. Oral alkalinization to prevent metabolic acidosis was used in 49 of 73 patients (67.1%). Two patients who refused any oral medication developed metabolic acidosis. The Mainz group concluded that the overall complication rate was low and comparable with that of other techniques of continent urinary diversion.

Woodhouse and Christofides (1998) reported on their experience with the Mainz II pouch in 15 primary cystectomy patients and 4 patients with prior standard ureterosigmoidostomy who were incontinent. They reported excellent results: 14 of 15 (93.3%) of the primary patients achieved documented daytime and nighttime urinary control, and the remaining patient refused follow-up but reported continence. The 4 patients undergoing a salvage procedure fared less well. Only 2 patients became continent, and the remaining 2 were found to be in chronic retention. Their failed continence was believed to be secondary to inadequate pouch emptying. Similarly, excellent results have been achieved by Venn and Mundy (1999). They reported full daytime and nighttime urinary continence in 14 of 14 patients and no major postoperative complications.

Bastian et al. (2004) have reported on the health-related quality of life in 83 patients undergoing Mainz II urinary diversion. They found that quality of life was similar to that of age-matched controls except for diarrhea symptoms, with 100% daytime continence.

There appears to be no metabolic advantage to this procedure, because the need for oral alkalinization is similar to that with standard ureterosigmoidostomy. In fact, the only difference between this operation and standard ureterosigmoidostomy is the partial reconfiguration of the rectosigmoid junction. It does appear that the reduced intracolonic pressures that result from the partial reconfiguration increase the sigmoid capacity and result in better daytime and nighttime continence. Whether the increased capacity and lower pressure of this pouch will decrease the incidence of upper tract complications remains to be determined by longer follow-up.

Continent Catheterizing Pouches

Numerous operative techniques have been developed for continent diversion, wherein urine is emptied at intervals by clean intermittent self-catheterization. Many of these operations are described in this chapter, although certain pioneering procedures that used intact bowel—such as those of Gilchrist et al. (1950), Ashken (1987), Mansson et al. (1984; Mansson, 1987), Benchekroun (1987), and others—are not. This is not to discredit the pioneers in the field but simply to allow this chapter to focus on those pouches that incorporate modern principles that attempt to achieve a spheric configuration and disruption of peristalsis.

In continent urinary diversion, the two favorite sites for stomal location are (1) at the umbilicus and (2) in the lower quadrant of the abdomen, through the rectus bulge and below the “bikini line.” This location is often preferred because it affords men and women the opportunity to conceal the stoma. The umbilicus is a preferred location for the individual confined to a wheelchair and has been reported to have a lower incidence of stomal stenosis, especially when an appendiceal stoma is fashioned. The umbilical location is also far easier for the paraplegic individual to catheterize without the need for chair transfer and disrobing. In individuals with a recessed umbilicus, the umbilical location of a stoma is barely perceptible from a normal umbilical dimple. In general, the stoma site is covered with a gauze pad or square bandage to avoid mucous soiling of clothing. Patients undergoing continent urinary diversion to an umbilical location should be advised to wear a medical alert bracelet that informs the examiner of the umbilical stoma.

Before the extension of orthotopic neobladder construction to women, there was some enthusiasm for the orthotopic placement of a catheterizing portal. This procedure has been carried out in certain female patients with success. The construction of a neourethra to the introitus is feasible, provided there is no substantial difficulty in the catheterizing process. However, because it can be difficult to direct a catheter through the “chimney” of an intussuscepted nipple valve, those continent diversions employing nipple valves are not particularly adaptable to orthotopic location, although they have been performed with success in a small number of patients (Olsson, 1987). In contrast, the imbricated and tapered ileal segment leading to an Indiana pouch is relatively easier to catheterize and can be used for orthotopic catheterizing diversion (Rowland et al., 1987). However, it may be difficult to obtain sufficient mesenteric length in some patients. The appendix can also be used as a neourethra, in which case mesenteric length should become less of a problem (Hubner and Pfluger, 1995).

Four general techniques have been employed to create a dependable, catheterizable continence zone. For right colon pouches, appendiceal tunneling procedures are the simplest of all to perform, because they use established surgical techniques already present in the urologic armamentarium. The in situ or transposed appendix is tunneled into the cecal taenia in a fashion similar to ureterocolonic anastomosis. Appendiceal continence mechanisms have been criticized for three general reasons. First, the appendix may be unavailable in some patients because of prior appendectomy. For those individuals, techniques have been developed that allow for the construction of a similar tube fashioned from ileum (Woodhouse and MacNeily, 1994) or from the wall of the right colon (Lampel et al., 1995a). Second, the appendiceal stump may be too short to reach the anterior abdominal wall or umbilicus while sufficient length is still maintained for tunneling. This criticism has been addressed by an operative variation described by Mitchell, in which the appendiceal stump can be lengthened by the inclusion of a tubular portion of proximal cecum (Burns and Mitchell, 1990; Fig. 140.3). This lengthening procedure has the added advantage of allowing for a slightly larger stoma made of cecum that is less prone to stomal stenosis. Appendiceal continence mechanisms share the feature of allowing only small-diameter (14- to 16-Fr) catheters to be used for intermittent catheterization; the large amount of mucus produced by an intestinal reservoir is more easily emptied or irrigated with use of a 20- to 22-Fr catheter. We believe that these criticisms are more theoretical than real and that the appendiceal or pseudoappendiceal continence mechanism remains a very attractive and reliable continence mechanism.

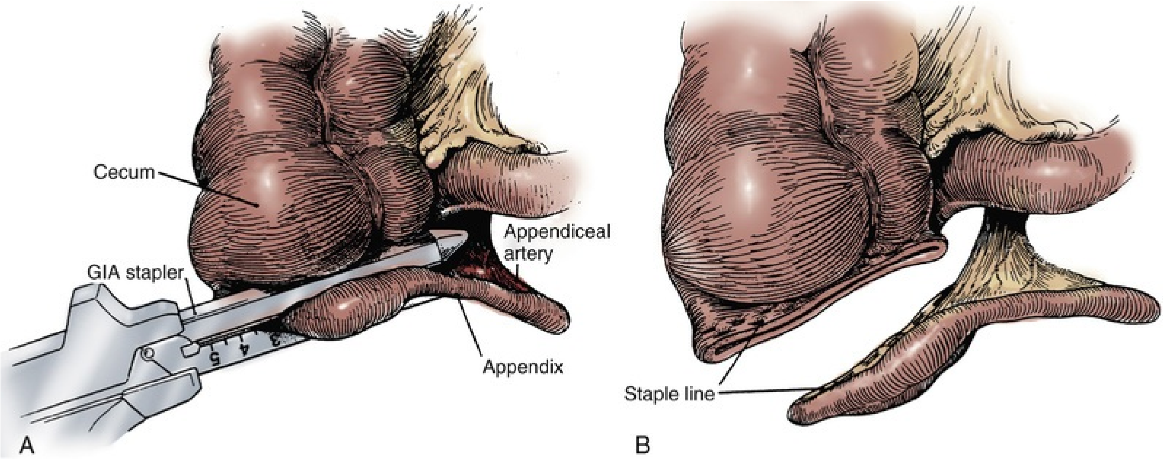

FIG. 140.3 (A) The appendiceal stump is lengthened by the inclusion of a tubular portion of proximal cecum by the application of the gastrointestinal anastomosis (GIA) stapler to the terminal cecum. A window is made in the mesoappendix, and the blade of the GIA stapler is advanced through the window. This maneuver ensures that the blood supply is not inadvertently damaged. (B) The added length is demonstrated. The appendix is rotated and implanted into the taenia; the cecal tube serves as the stoma. (From Burns MW, Mitchell ME: Tips on constructing the Mitrofanoff appendiceal stoma. *Contemp Urol* 2:10–12, 1990.)

The second major type of continence mechanism used in right colon pouches is the tapered and/or imbricated terminal ileum and ileocecal valve. Here again the technique is rather simple, with imbrication or plication of the ileocecal valve region along with tapering of the more proximal ileum in the fashion of a neourethra (Bejany and Politano, 1988; Lockhart, 1987; Rowland et al., 1985). These techniques afford a reliable continence mechanism.

One feature of right colon pouches that has been criticized is the loss of the ileocecal valve. Although this does result in an increased frequency of bowel movements for some patients in the short term, the majority will experience bowel regularity either through intestinal adaptation or with the use of pharmacologic therapy. However, some patients have developed rather striking diarrhea or steatorrhea after the loss of the ileocecal valve. This may be particularly true in pediatric patients in whom there is neurogenic bowel dysfunction (e.g., myelomeningocele).

The third surgical principle in constructing the continence mechanism is the use of the intussuscepted nipple valve or the flap valve, which avoids the need for intussusception. The creation of nipple valves is by far the most technologically demanding of all the continence mechanisms, and it is associated with the highest complication and reoperation rates. There exists a significant learning curve before the surgeon achieves reproducible and dependable results. For this reason, nipple valve construction should probably not be chosen by the surgeon carrying out occasional construction of continent pouches. Furthermore, in the past three decades we have seen the introduction of numerous modifications of the original technique of Kock for construction of a stable nipple valve. The singular reason for all of these modifications is the rather disappointing long-term stability of the nipple valve in some patients. As a result, the group at the University of Southern California has developed the T pouch, which uses a flap valve (Stein et al., 1998). This procedure, which appears much simpler than the intussuscepted nipple valve, has been used to create a continence and an antireflux mechanism. Nipple valve failure from slippage or valve effacement can be anticipated in 10% to 15% of cases even in the hands of the very best and experienced surgeons. In addition to slippage, nipple valves are subject to ischemic atrophy. When this occurs, a new nipple valve must be fashioned from a new bowel segment.

A final feature of stapled nipple valves is the potential for stone formation on exposed staples. This was greatly lessened by the omission of staples at the tip of the intussuscepted nipple valve, as suggested by Skinner et al. (1984). However, more proximal staples occasionally erode into the pouch and serve as a nidus for stone formation. These stones are usually manageable endoscopically with forceps extraction, or else with electrohydraulic or ultrasonic disintegration of the stone with subsequent forceps extraction of the staple. Although exposed staples may serve as a nidus for stone formation, continent urinary diversion results in more urinary excretion of calcium, magnesium, and phosphate as compared with ileal conduit diversion (Terai et al., 1995). Thus all patients undergoing continent diversion are at an increased risk for the formation of reservoir stones.

The fourth major technique for constructing a continence mechanism is the provision of a hydraulic valve, as in the Benchekroun nipple (Benchekroun, 1987). In this procedure a small bowel segment is isolated, with subsequent reversed intussusception that effectively apposes the mucosal surfaces of the segment. Tacking sutures are placed on a portion of the circumference of the intussuscepted segment to stabilize the nipple valve while allowing urine to flow freely between the leaves of apposed ileal mucosa. As the pouch fills, hydraulic pressure closes the leaves, thereby ensuring continence. The premise of this technique is that as the reservoir fills, the pressure within the valve would also increase, resulting in continence. Concerns regarding stomal stenosis, especially in children, and nipple destabilization have resulted in this procedure being largely abandoned (Sanda et al., 1996). As a result, it is not discussed further in this chapter.

General Procedural Methodology

During construction of the pouch, intraoperative testing for pouch integrity should always be performed. The continence mechanism is also tested for ease of catheterization as well as continence after the pouch construction has been completed. The pouch is filled with saline, the continence mechanism catheter is removed, and the pouch is compressed lightly to look for points of leakage as well as to test the continence mechanism for its ability to contain urine. **Thereafter the continence mechanism is catheterized to ensure ease of catheter passage. This is an extremely important and crucial maneuver because the inability to catheterize is a serious complication that will often result in the need for reoperation.** If the surgeon cannot easily catheterize in the operating room, the patient is unlikely to be able to easily catheterize postoperatively. In general, all redundancy should be removed from the continence mechanism. It is often useful to secure the reservoir to the anterior abdominal wall in a manner that prevents the reservoir from migrating. This can prevent the development of a false passage or a kink, thereby facilitating catheterization.

Postoperatively, the larger-bore catheter used for drainage of the pouch should be irrigated at frequent intervals to prevent mucous obstruction. This can be performed at 4-hour intervals by irrigation with 45 to 50 mL of saline. Less frequent intervals of irrigation can be employed when the urine is totally diverted from the kidneys by means of long indwelling stents. It is essential that as soon as possible the patient be taught how to self-irrigate and that he or she understand the required regimen. This not only familiarizes the patients with the catheterization process but also reduces the work burden on the nursing staff and allows for earlier discharge.

If the patient is on a positive nitrogen balance (i.e., eating a regular diet), a contrast study may be performed on the seventh postoperative day to ensure pouch integrity. If no leaks are noted, ureteral stents can be removed. When it has been ascertained that the ureteral anastomoses and pouch are intact, the suction drain is removed. The suprapubic tube (if employed) can also be removed at this time, but we prefer leaving it in place until the patient is confident with self-catheterization. The patient is taught to irrigate the tube traversing the continence mechanism at 4-hour intervals and whenever any episode of intra-abdominal pressure or discomfort is experienced. Once these procedures have been mastered and the patient is tolerating a regular diet, the patient can be discharged, usually at hospital days 6 to 8.

The following represents a summary of common patient questions and everyday solutions:

- *What kind of catheter do I use?* For nipple valves, a straight-ended 22- to 24-Fr tube; for ileocecal plication, a 20- to 22-Fr coudé-tipped catheter; and for appendiceal sphincters, a 14- to 16-Fr coudé-tipped catheter
- *How do I carry my catheter?* If single-use disposable catheters are not obtainable (most medical insurance companies now cover such supplies), a reusable catheter can be placed in a zipper-locked bag that can be placed in a women's purse or a man's coat pocket.
- *How do I clean the stoma before catheterizing in a public facility?* With a topical antiseptic wipe (e.g., with benzalkonium chloride), which can be purchased in individually wrapped packets.
- *How do I lubricate the catheter?* By tearing off the end of an

individual-use foil pack of water-soluble lubricant and inserting the tip of the catheter into the pack. Many catheters are now available in self-lubricating single-use packaging.

- *What do I do with the stoma after catheterizing?* Cover it with a bandage.
- *How do I clean my catheter after draining my pouch?* By rinsing with ordinary tap water through the inside channel and over the outside surface before replacing the catheter in its zipper-locked bag. It remains preferable to use single-use sterile catheters, even though continent reservoirs are chronically colonized.

In the case of ileal pouches, pouch capacity will initially be low (150 mL). Therefore the frequency of catheterization will have to be significantly different in these individuals compared with those with right colon pouches, in which initial comfortable capacities will be in excess of 300 mL. To ensure restful sleep, the smaller-capacity pouches may be managed best with indwelling catheterization during sleeping hours.

General Care

Because all patients with catheterized pouches will have chronic bacteriuria, the problem of antibiotic management should be discussed. **Most authors would suggest that bacteriuria in the absence of symptoms in patients with a urinary diversion does not warrant antibiotic treatment** (Skinner et al., 1987; Suriano et al., 2008). The construction of an effective antireflux mechanism in these pouches may help protect against clinical episodes of pyelonephritis, in contrast to patients with freely refluxing conduits. Obviously, if clinical pyelonephritis does occur, antibiotic treatment should be instituted. Episodes of recurrent pyelonephritis should be evaluated with radiography of the pouch to diagnose failure of the antireflux mechanism, upper tract stone formation, or ureteral stenosis.

A condition termed “pouchitis” has been described that manifests with pain in the region of the pouch along with increased pouch contractility. This condition, although infrequent, may result in temporary failure of the continence mechanism because of the hypercontractility of the bowel segment employed for construction of the pouch. The patient typically has a history of sudden explosive discharge of urine through the continence mechanism (rather than dribbling incontinence), along with discomfort in the region of the pouch. Appropriate antibiotic therapy usually results in resolution of these symptoms. It has been our experience that short courses of antibiotics are not usually successful in treating pouch infections. This may be because of the larger amount of foreign material in the form of mucus and sediment within intestinal pouches as opposed to the bladder. Intestinal crypts may also serve as bacterial sanctuaries. Therefore, whenever a pouch infection is diagnosed, antibiotic therapy should be continued for at least 10 days. Pyelonephritis will, of course, require longer courses of therapy.

Urinary retention is an infrequent but serious occurrence in catheterizable pouches. It is most commonly seen with pouches with continence mechanism consisting of a nipple valve. In these circumstances, when the chimney of the nipple valve is not near the abdominal surface, the catheter may be misdirected into folds of bowel rather than into the nipple valve proper, resulting in urinary retention. **Pouch urinary retention represents a true emergency, and the patient must seek immediate attention so that catheterization and drainage by experienced personnel can be achieved promptly.** The use of a coudé-tipped catheter may be helpful. Rarely, use of a flexible cystoscope will be necessary with passage of a guide wire into the reservoir followed by a Council catheter. After the immediate problem has been resolved by emptying the pouch, a catheter should be left indwelling for 3 to 5 days to allow the edema and trauma to the catheterization portal to resolve. Before discharge, the patient should be observed to successfully self-catheterize on multiple occasions. The appropriate angle of entry is highly variable and individualized. If used, proper use of the angled coudé catheter should be taught to patients until they are comfortable with its use. In fact, we prefer to routinely use coudé catheters with non–nipple valve pouches.

Intraperitoneal rupture of catheterizable pouches has been reported (Kristiansen et al., 1991; Thompson and Kursh, 1992; Watanabe et al., 1994). In general, these episodes are more common in the neurologic patient in whom sensation of pouch fullness may be less distinct (Hensle, personal communication, 1993; Mitchell, personal communication, 1993). Ruptures may also be associated with mild abdominal trauma, such as a fall. In general, these patients require immediate pouch decompression and radiographic pouch studies. For patients with large defects, surgical exploration and pouch repair are required. If the amount of urinary extravasation is small and the patient does not have evidence of peritonitis, catheter drainage and antibiotic administration may suffice in treating an intraperitoneal rupture. Patients managed with this conservative approach require careful monitoring. If there is any sign of progressive peritonitis, surgical exploration and repair are imperative. We have successfully employed this nonoperative approach on patients with ruptured right colon pouches.

Continent Ileal Reservoir (Kock Pouch)

This operation was first reported for use in urinary diversion by Kock et al. in 1982. This report was singularly responsible for the renewed interest in continent diversion procedures at that time. An outgrowth of the Kock procedure for continent ileostomy (Kock, 1971), the Kock pouch combined reasonably dependable techniques for ensuring urinary continence and preventing reflux to the upper urinary tracts (nipple valves) with carefully refashioned bowel that provided a low-pressure urinary reservoir. This procedure and the similarly constructed T pouch are the only catheterizable continent diversions that preserve the ileocecal valve. **Skinner and his coworkers** (Skinner, 1992; Skinner et al., 1989) **have carefully studied and improved the technique over the years while amassing prodigious experience with the operation and its variants. The high complication rate and the technical difficulties involved with constructing this reservoir have resulted in the procedure being abandoned by most individuals.** As a result, this procedure is not discussed further in this edition. Those interested in a more detailed description should refer to our chapter in previous editions of this text. However, the construction of a Kock limb remains an important procedure for use in repairing failed continence or reflux mechanisms and as such is described in more detail. It is Skinner's operative description that is followed closely in this chapter.

Procedure.

A 15- to 20-cm length of ileum is selected for creating the intussuscepted nipple valve. The proximal 10 cm serves as the valve, and the distal 5 to 10 cm serves as the patch (Fig. 140.4A). The distal length is chosen based on the volume lost after resection of the failed mechanism. Only 5 cm is necessary for the patch, but on some occasions the reservoir may require augmentation. The middle 6 to 8 cm of the 10-cm segment is denuded of mesentery by electrocoagulation. An Allis or Babcock clamp is advanced into the ileal terminus, grasping the full thickness of the intussusceptum and inverting the ileum into the pouch (Fig. 140.4B). Using the TA-55 stapler, three rows of 4.8-mm staples are applied to the intussuscepted nipple valve (Fig. 140.4C). The distal six staples from each cartridge are removed before staple application to ensure that the tip of the valve is free of staples. Most authors suggest that the pin of the stapling instrument should always be kept in place so that staple misalignment does not occur. This will result in a pinhole puncture site at the base of the nipple valve that should be oversewn with absorbable suture material to prevent fistula formation after staple application is complete. The nipple valve is then fixed to the back wall of the patch by one of two stapling techniques (Skinner et al., 1984). A small buttonhole may be made in the back wall of the ileal plate so that the anvil of the stapler can be passed through the buttonhole and advanced into the nipple valve before application of the fourth row of staples (Fig. 140.4D). If this is carried out, the buttonhole is oversewn afterward with absorbable material. Alternatively, the anvil of the stapler can be directed between the two leaves of the intussuscipiens and the fourth row of staples used to fix the inner leaf of the nipple valve to the pouch wall (Fig. 140.4E).

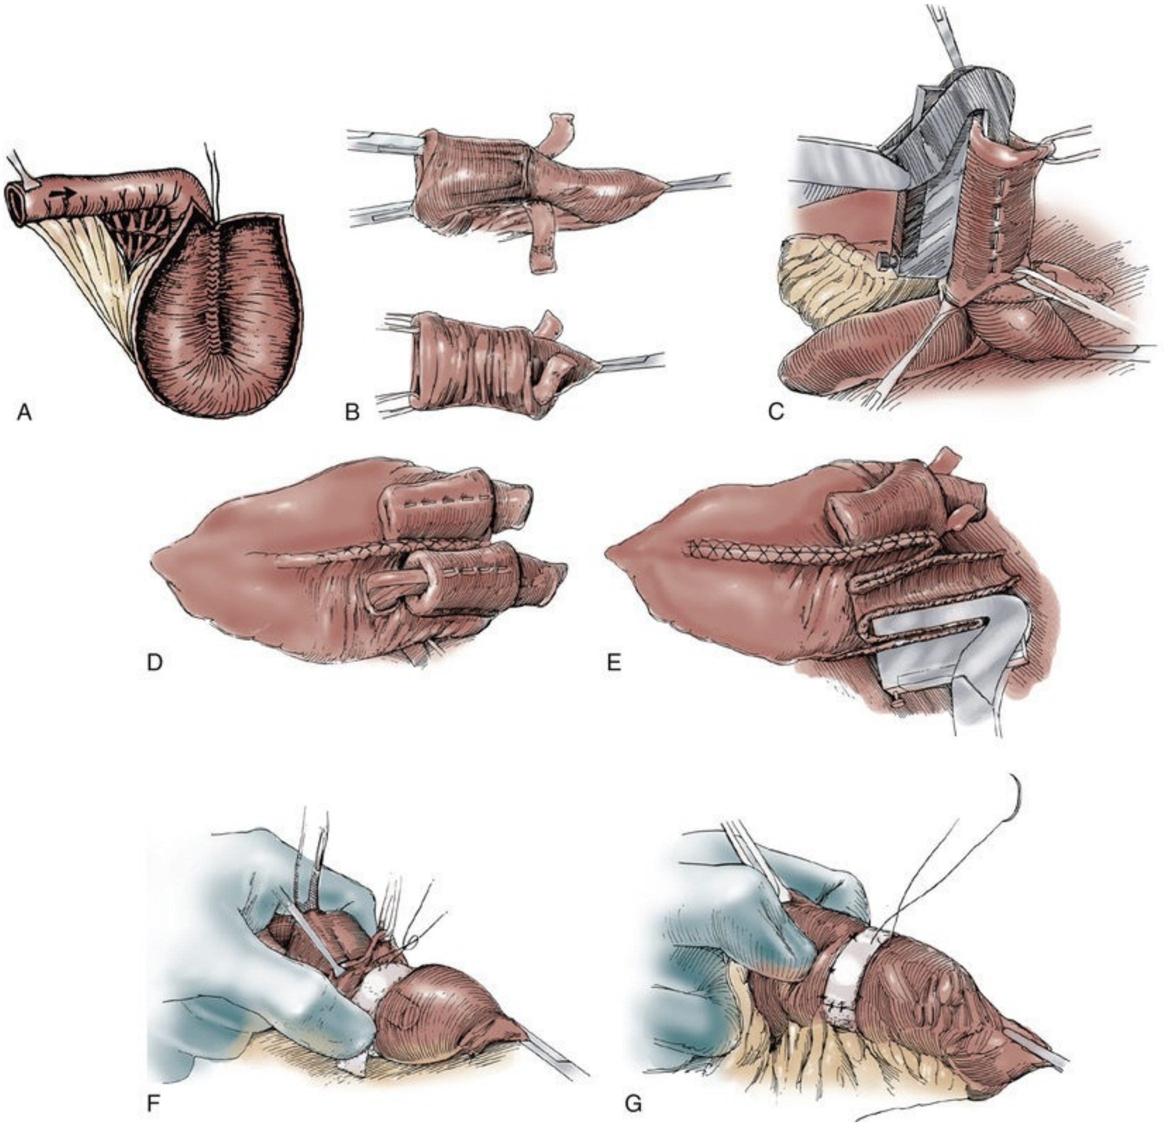

FIG. 140.4 (A) A 15-cm segment of terminal ileum is isolated and opened along its antimesenteric wall. The proximal 10 cm will serve as the continent intussusception and the distal 5 to 10 cm as the patch. The size of the patch will vary according to the size of the excised segment. (B) An Allis or Babcock clamp is advanced into the ileal terminus; the full thickness of the intussuscipiens is grasped, and it is prolapsed into the pouch. (C) Three rows of 4.8-mm staples are applied to the intussuscepted nipple valve using the TA-55 stapler. (D) A small buttonhole is made in the back wall of the ileal plate to allow the anvil of the TA-55 stapler to be passed through and advanced into the nipple valve. A fourth row of staples is applied. The figure shows two valve mechanisms, but in this instance there would be only one. (E), The anvil of the stapler can be directed between the two leaves of the intussuscipiens and the fourth row of staples applied in this manner. Two valve mechanisms are shown, but in this instance there would be only one. (F) A 2.5-cm–wide strip of absorbable mesh is placed through additional windows of Deaver at the base of each nipple valve. The mesh strips are fashioned into collars. (G) The collars are sewn

to the base of the pouch as well as to the ileal terminus with seromuscular sutures. (A, From Ghoneim MA, Lock NG, Lycke G, et al.: An appliance-free, sphincter-controlled bladder substitute. *J Urol* 138:1150–1154, 1987. B to G, From Hinman F Jr: *Atlas of urologic surgery,* Philadelphia, 1989, Saunders.)

Some authors, including Skinner et al. (1989), suggest the use of an absorbable mesh collar to anchor the base of the nipple valve. If a collar is used, a 2.5-cm-wide strip of absorbable mesh is placed through an additional window of Deaver at the base of the nipple valve. The mesh strip is fashioned into a collar and sewn to the base of the patch with seromuscular sutures of absorbable material (Figs. 140.4F and G). The patch is then sewn to the reservoir.

Double T Pouch

As indicated earlier, many surgeons have abandoned the Kock pouch largely because of the technical difficulties of creating the continence and antireflux mechanisms and the high complication rates associated with them. This should not be viewed as a condemnation of the pioneering work of Kock and his associates. Without their initial efforts, many of the procedures described in this chapter would never have come into being. Rather, this represents the natural evolution of surgical techniques.

The group at the University of Southern California modified a technique described by Abol-Enein and Ghoneim (1993, 1994) to create a novel continence mechanism created entirely from ileum (Bochner et al., 1988). Abol-Enein and Ghoneim (1994) described a technique that created an extramural serosal tunnel into which the ureters were implanted. This extramural trough created a pseudotunnel that prevents reflux but in theory is associated with a lower risk of obstruction than the Goodwin et al. (1958), Leadbetter and Leadbetter (1961), or LeDuc et al. (1987) techniques of direct transmural ureteral implantation. Stein et al. (1998) first reported on the use in a neobladder of a tapered ileal segment implanted into a serosal trough as the antireflux mechanism. In 1999 they reported on their adaptation of the technique to the ileal-anal reservoir. Also in 1999 they presented their early experience with a double T pouch as a replacement for the Kock pouch at the meeting of the American Urological Association (Stein et al., 1999a), and they published their findings in 2001 (Stein and Skinner, 2001). Their technique is presented in this section.

Procedure.

A 70-cm segment of terminal ileum is isolated 15 to 20 cm from the ileocecal valve at the line of Treves. The proximal isoperistaltic 10- to 12-cm segment is isolated and will serve as the antireflux mechanism. The distal 12- to 15-cm segment is isolated and rotated in an antiperistaltic fashion and will create the cutaneous continence mechanism (Figs. 140.5A and B). A short 2- to 3-cm mesenteric incision is made to isolate the proximal limb, and a 4-cm incision is made for the distal limb, thereby preserving the major vascular arches. The proximal and distal segments can vary in length, depending on ureteral length and the thickness of the anterior abdominal wall. The middle 44 cm of ileum is folded in a W with each limb measuring 11 cm.

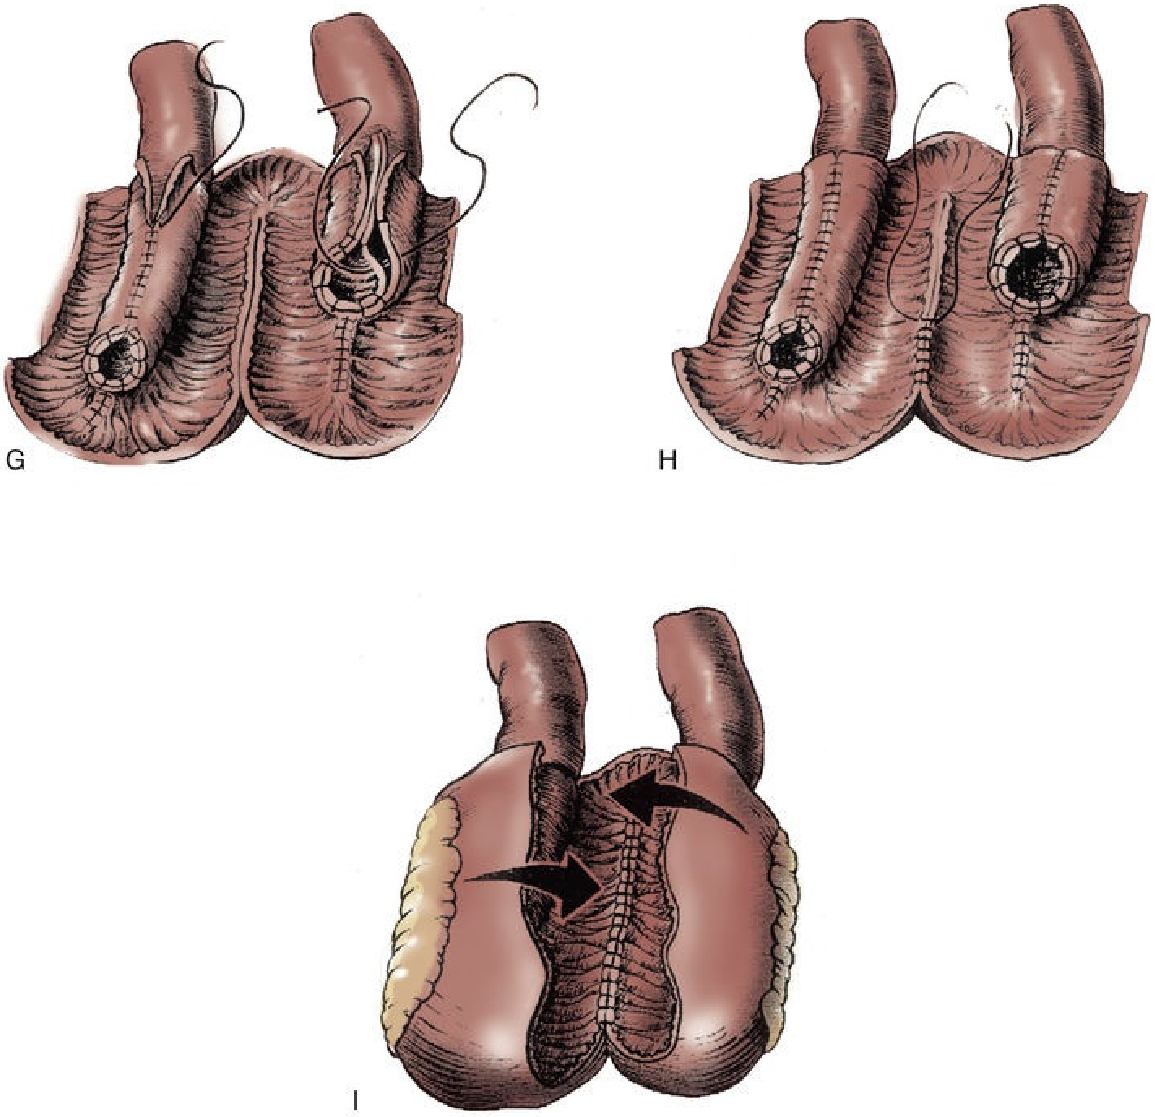

FIG. 140.5 (A) A 70-cm segment of terminal ileum is isolated 15 to 20 cm from the ileocecal valve. (B) A proximal 10-cm segment is isolated and rotated toward what will become the reservoir in an isoperistaltic direction. The distal 12 to 15 cm is rotated toward the reservoir in an antiperistaltic direction. (C) The windows of Deaver are opened to allow the walls of the W reservoir to be apposed behind the valve mechanisms. Penrose drains are passed to guide suture passage. (D) Horizontal mattress sutures of 3-0 silk are passed through each window. The distal continence mechanism is longer than the proximal antireflux mechanism. (E) The proximal and distal mechanisms are tapered with a metal gastrointestinal anastomosis stapler. (F) The bowel is incised along its antimesenteric border where it will overlie the two Ts. Distal to the Ts, the bowel is incised close to the approximated limbs of the reservoir. (G) The ostia of the valves are secured to the bowel wall with interrupted absorbable sutures. The two flaps of ileum are closed over the Ts with running absorbable sutures. (H) The back wall of the reservoir is closed with running absorbable sutures. (I) The lateral walls are folded medially, and the construction is completed with running absorbable

sutures. (From Stein JP, Buscarini M, DeFilippo RE, et al.: Application of the T pouch as an ileo-anal reservoir. *J Urol* 162:2052–2053, 1999.)

The afferent antireflux mechanism is created by opening the windows of Deaver between the vascular arcades along the distal 3 to 4 cm. The efferent continence mechanism is created by opening the proximal 7 to 8 cm of vascular arcades (antiperistaltic) (Fig. 140.5C). One-fourth–inch Penrose drains are then placed in each window of Deaver to facilitate the passage of the 3-0 silk horizontal mattress sutures that are used to approximate the serosa of the corresponding 11-cm limbs of the W (Fig. 140.5D). The 3- to 4-cm anchored portion of the proximal limb is then tapered over a 30-Fr catheter, and the 7- to 8-cm anchored portion of the efferent limb is tapered over a 16-Fr catheter. In both instances, tapering is performed with a gastrointestinal anastomosis (GIA) stapler (the staples will not be in contact with urine). Care must be taken in the efferent limb to create a gradual taper so that the catheter does not hit a false cul-de-sac (Fig. 140.5E). The portions of the 11-cm W limbs not forming the troughs are then sutured together with a running 3-0 polyglycolic acid (PGA) suture. The bowel is now incised along its antimesenteric border in the portion where the serosal trough exists and in proximity to the medial PGA suture lines when beyond the two limbs (Fig. 140.5F). The incised mucosa is then closed in two layers with a running suture of 3-0 PGA. The incised intestinal flaps (antimesenteric incision) are then sutured to each ostium with interrupted sutures of 3-0 PGA, and the two ileal flaps are sutured over each segment with a running suture of 3-0 PGA (Fig. 140.5G). The reservoir is then closed side to side in two layers with 3-0 PGA, thereby completing its construction (Figs. 140.5H and I). The ureters are anastomosed end to side over stents to the proximal limb, which has been closed with a running absorbable Parker-Kerr suture. The efferent limb is then brought to the abdominal wall stoma site, and redundant ileum is resected. The stoma is then matured with the reservoir lying immediately adjacent to the anterior abdominal wall.

Postoperative Care and Comments.

Postoperative care is similar to that for any continent reservoir. Stein et al. (1999b) initially reported on 9 patients, 7 of whom could be evaluated for continence and long-term complications and 2 of whom died of disease during follow-up. All 7 patients achieved immediate continence upon catheter removal. However, 2 patients later became incontinent, with 1 requiring surgical revision. None of the 9 patients experienced an early postoperative complication. One patient developed a reservoir stone 9 months after surgery that was removed endoscopically without sequelae. Pouch capacity was excellent: 400 to 700 mL (average, 500 mL). There was no radiographic evidence of reflux in any patient, and there was no upper tract deterioration. This operative procedure appears to have many advantages over the Kock pouch, and good long-term continence results have been reported. Marino et al. (2002) reported on 18 patients with 1-year follow-up with 100% daytime and nighttime continence and no delayed complications. Seifert et al. (2008) published their results on 19 patients who underwent ileal double T pouch construction between 1998 and 2006. Five patients (26%) had complications related to the diversion, some of which required surgical revision. Three patients (16%), all of whom had a body mass index exceeding 30, developed necrosis of the efferent loop and subsequent cutaneous fistulae. Sixteen (84%) eventually developed daytime and nighttime continence. Although mild acidosis was common in this group, no urinary reflux was detected, and no patients had significant upper tract deterioration or pyelonephritis.

Mainz Pouch I

The catheterizable Mainz pouch has undergone considerable modification over the years (Gerharz et al., 1997; Lampel et al., 1996; Stein et al., 1995; Thüroff et al., 1985, 1988, 2010). **The main impetus for these changes has been the difficulty encountered with the nipple valve mechanism.** The operative technique has now been modified to use the intact ileocecal valve as a means of further stabilizing the intussusception (Thüroff et al., 1988). This procedure is described here without further reference to earlier prototypes.

Procedure.

The catheterizable Mainz pouch varies somewhat from the orthotopic, voiding Mainz pouch. First, a longer segment of bowel is used. A 10- to 15-cm portion of cecum and ascending colon is isolated along with two separate, equally sized limbs of distal ileum and an additional portion of ileum measuring 20 cm (Fig. 140.6A). The entire colon and distal segments of ileum are spatulated, taking care to preserve the ileocecal valve. These three bowel segments are folded in the form of an incomplete W, and their posterior aspects are sutured to one another to form a broad posterior plate (Fig. 140.6B). A portion of the intact proximal ileal terminus is freed of its mesentery for a distance of 6 to 8 cm, and intussusception of the segment is achieved. Two rows of staples are applied on the intussusceptum (Fig. 140.6C). Thereafter, the intussuscipiens is led through the intact ileocecal valve and a third row of staples is applied to stabilize the nipple valve to the ileocecal valve (Fig. 140.6D). Finally, a fourth row of staples is applied inferiorly, securing the inner leaf of the intussusception to the ileal wall (Fig. 140.6E).

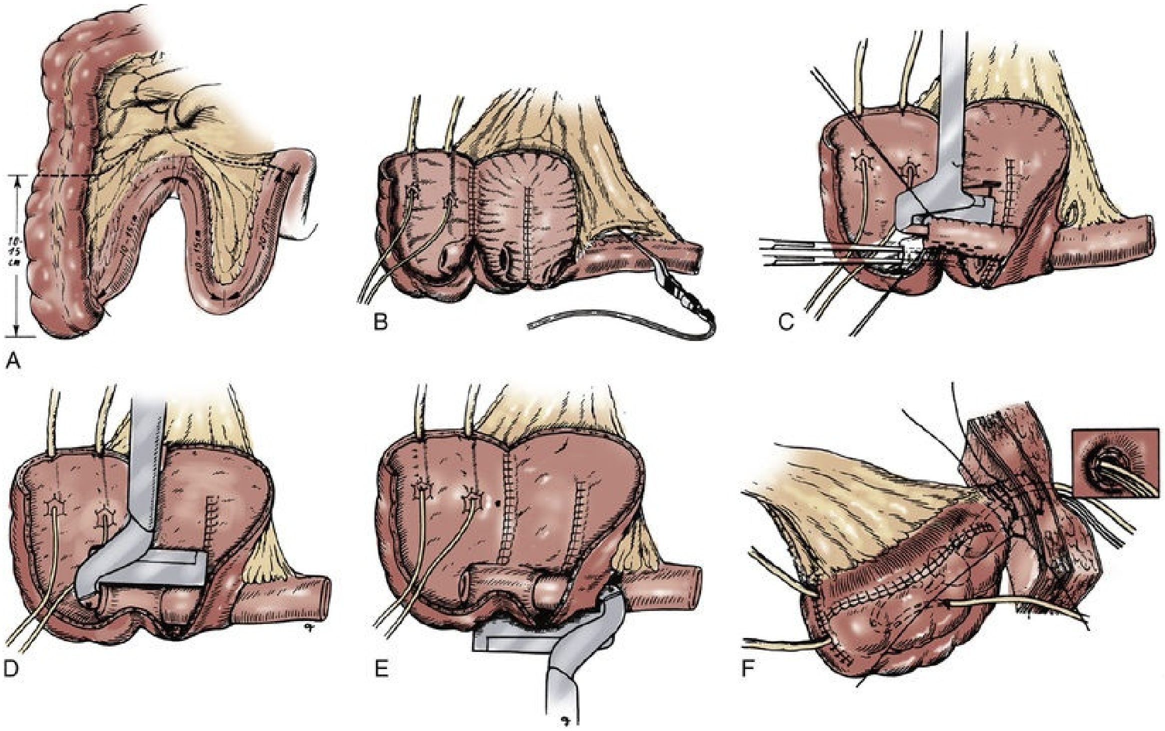

FIG. 140.6 (A) A 10- to 15-cm portion of cecum and ascending colon is isolated along with two separate equal-sized limbs of distal ileum and an additional portion of ileum measuring 20 cm. (B) A portion of the intact proximal ileal terminus is freed of its mesentery for a distance of 6 to 8 cm. (C) The intact ileum is intussuscepted, and two rows of staples are taken on the intussuscipiens. (D) The intussuscipiens is led through the intact ileocecal valve, and a third row of staples is taken to stabilize the nipple valve to the ileocecal valve. (E) A fourth row of staples is taken inferiorly, securing the inner leaf of the intussusception to the ileal wall. (F) A button of skin is removed from the depth of the umbilical funnel, and the ileal terminus is directed through this buttonhole. Excess ileal length is resected and ileum is sutured at the depth of the umbilical funnel. (A, From Thüroff JW, Alken P, Hohenfellner R: The Mainz pouch [mixed augmentation with ileum ‘n’ cecum] for bladder augmentation and continent diversion. In King LR, Stone AR, Webster GD, editors: *Bladder reconstruction and continent urinary diversion,* Chicago, 1987, Year Book, p 252; B to F, From Thüroff JW, Alken P, Riedmiller H, et al.: 100 cases of Mainz pouch: continuing experience and evolution. *J Urol* 140:283–288, 1988.)

Ureterocolonic anastomoses are created at the apex of the reservoir, which is then folded on itself in a side-to-side fashion to complete pouch construction. The entire pouch is rotated cephalad so as to bring the ileal terminus to the region of the umbilicus. A small button of skin is removed from the depth of the umbilical funnel, and the ileal terminus is directed through this buttonhole (Fig. 140.6F). The pouch is secured to the posterior fascia with interrupted absorbable sutures, and the ileal terminus is sewn similarly to anterior fascia. Excess ileal length is resected, and the ileum is sutured at the depth of the umbilical funnel with interrupted absorbable sutures.

Postoperative Care and Comments.

No specific differences in postoperative care or complications associated with the Mainz pouch must be addressed. Initial pouch capacities are higher than with the Kock or T pouch. Final mean capacity averaging more than 600 mL has been reported. Pouch pressures are 23 cm H_2O at half capacity and 31 cm H_2O when the pouch is full. Contraction waves beginning at 50% pouch fullness can be recorded at an amplitude of 12 cm H_2O. Thus this pouch seems to produce a reasonably low-pressure urinary reservoir, although the pressures are not as low as those achieved with the use of small bowel alone.

The 10- and 12-year experiences with the Mainz pouch and the variations created by its developers have been described (Lampel et al., 1996; Stein et al., 1995). From 1983 to 1994, 440 patients underwent a Mainz I operation in two urology departments, Mainz and Wuppertal. Continence mechanisms varied: in 146 patients the appendix was used as the continence mechanism; in 270 patients the intussuscepted nipple was used as the continent stoma; in 14 patients a submucosal, seromuscular bowel flap was used; and in 10 patients a submucosal full-thickness bowel flap was used. The early complication rate was 12% and included mechanical ileus requiring open revision in 9 patients (1.6%), pouch leakage requiring revision in 5 patients (0.9%), wound dehiscence in 4 patients (0.7%), and fatal pulmonary emboli in 4 patients (0.7%).

The late complication rate was 37% and was predominantly attributable to the pouch. Stomal failure requiring open revision occurred in 45 patients (8%) and was directly related to the continence mechanism. Only 2 of 146 patients (1.4%) with an appendiceal continence mechanism were incontinent, but stomal stenosis occurred in 21%. The developers of this procedure were innovative in their attempts to bring the incontinence rate down to an acceptable level. To this end they tried multiple techniques, with variable success: an alloplastic stoma (4 of 4 incontinent), sutured intussusception (8 of 8 incontinent), stapled intussusception (5 of 22, 23% incontinent), and stapled ileocecal intussusception (10 of 204, 4.9% incontinent). The stapled ileocecal intussusception described previously is the current recommendation, and the long-term incontinence rate among the patients undergoing the stapled nipple valves was reduced to 10%. Other late complications included the need for ureteral reimplantation in 28 patients (4.9%), and stomal stenosis in 29 patients with an ileal nipple (11.7%) and in 17 patients with an appendiceal stoma (14.7%).

Calculus formation in the pouch occurred in 38 patients (6.8%), resulting in 36 percutaneous procedures. Despite the loss of the terminal ileum, no significant decrease in serum vitamin B_{12} levels has been reported, and no patient has developed macrocytic anemia or neurologic symptoms. However, 25% of patients are on oral alkalinization to avoid metabolic acidosis.

Since the inception of this procedure, the overall complication rate has been considered high (31%). However, as Stein et al. (1995) **pointed out, 50% of the complications were manageable with percutaneous techniques. In addition, since 1988 the incontinence rate has been only 3.2% and less than 2% in patients with an appendiceal mechanism.**

Gerharz et al. (1997) from Marburg, Germany, reported their single-institution experience with the Mainz I ileocecal pouch. From 1990 to 1996, 202 consecutive patients underwent continent diversion, 96 with a submucosally embedded in situ appendix and 106 with an intussuscepted ileal nipple. All patients had an umbilical stoma. In 172 of 200 patients (86%), no stomal complications occurred. In 17 of 96 patients (18%) with an appendiceal stoma, 23 revisions were performed for stomal stenosis. In contrast, only 13 of 106 patients (12%) with an intussuscepted ileal nipple developed problems with their stoma. However, these patients required more invasive, major procedures for correction, whereas those with an appendiceal stenosis could usually undergo repair with a minor procedure. Three patients with an ileal nipple (3%) developed pouch calculi, whereas none of the patients with an appendiceal continence mechanism developed stones. As a result, Gerharz et al. (1997) concluded that the appendix, when available, should be the intestinal continence mechanism of choice.

We share the enthusiasm for the use of the appendix as a continence mechanism. In our experience this technique has also been reliable and easy to perform. It has been our tendency in constructing right colon pouches involving an appendiceal continence mechanism to use the entire right colon inclusive of the hepatic flexure to form the reservoir, thereby preserving more terminal ileum. This has the theoretic advantage of fewer metabolic complications, but the Mainz group has not reported significant metabolic problems.

The introduction of the more reliable appendiceal continence mechanism has greatly increased the acceptance of the Mainz I procedure. The Mainz group has also developed two new techniques for construction of a Mitrofanoff, or appendiceal, type of tube for use in patients whose appendix is either unsuitable or absent (Lampel and Thüroff, 1998; Lampel et al., 1995a, 1995b). Both techniques use a small-caliber conduit fashioned from the large intestine in the region of the cecum. One technique uses a full-thickness tube lined by mucosa (Fig. 140.7) and the other a seromuscular tube lined by serosa (Fig. 140.8). Both techniques appear to be successful, although the full-thickness tube was associated with a lower complication rate and a higher success rate in the initial report (Lampel et al., 1995b). With longer follow-up, Lampel et al. (1995b) have observed similar success rates with both tubes; 93% of the patients with a seromuscular tube (25 of 27) and 92% of the patients with a bowel wall tube (22 of 24) were continent day and night (Lampel and Thüroff, 1998). The authors believed that either tube was reliable and that each had its own unique advantages and disadvantages. In general, the full-thickness bowel wall tube was more adaptable because of the ability to create a longer tube. However, this came at the expense of a more tenuous blood supply. The decreased distal blood supply may be improved by creating a wider base on the tube. This could, however, make taenial implantation more difficult. The seromuscular tube was equally reliable but could be anastomosed only to the umbilicus, because of the short adit tube. Either tube was believed to be indicated as a continence mechanism in the Mainz I pouch when the appendix was not available or as a continence mechanism for reservoirs created from other large intestinal segments. Either technique could be used as a salvage procedure when another primary continence mechanism had failed.

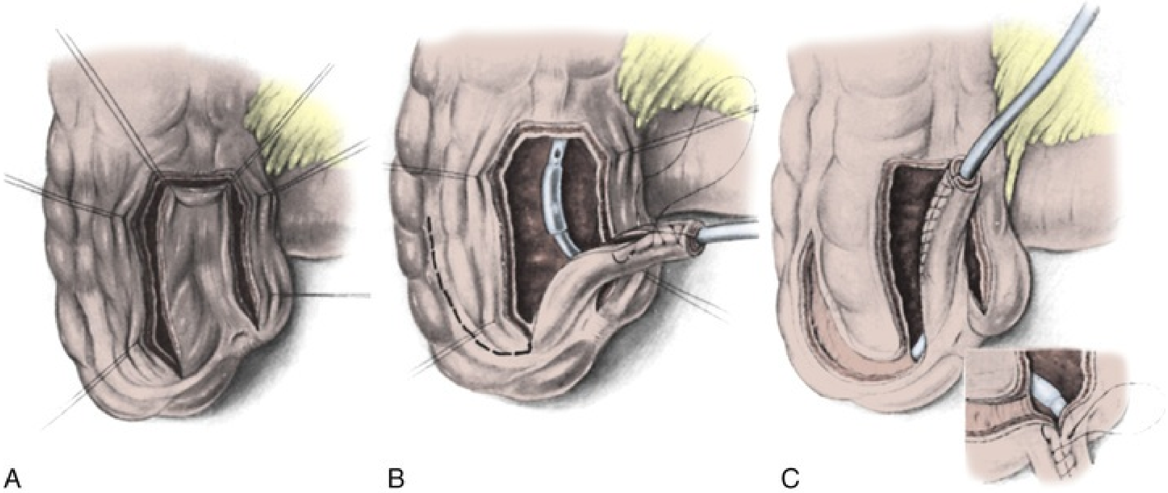

FIG. 140.7 (A to C) A full-thickness tube lined by mucosa is fashioned over an 18-Fr Foley catheter for tunneled reimplantation. The tube is closed with a running 3-0 absorbable suture. For longer tubes, we would advise a wider base to prevent distal ischemia. The continence mechanism is created by placing the tube into the adjacent taenial trough. (From Lampel A, Hohenfellner M, Schultz-Lampel D, Thüroff JW: In-situ tunneled bowel flap tubes: 2 new techniques of a continent outlet for Mainz pouch cutaneous diversion. *J Urol* 153:308–315, 1995.)

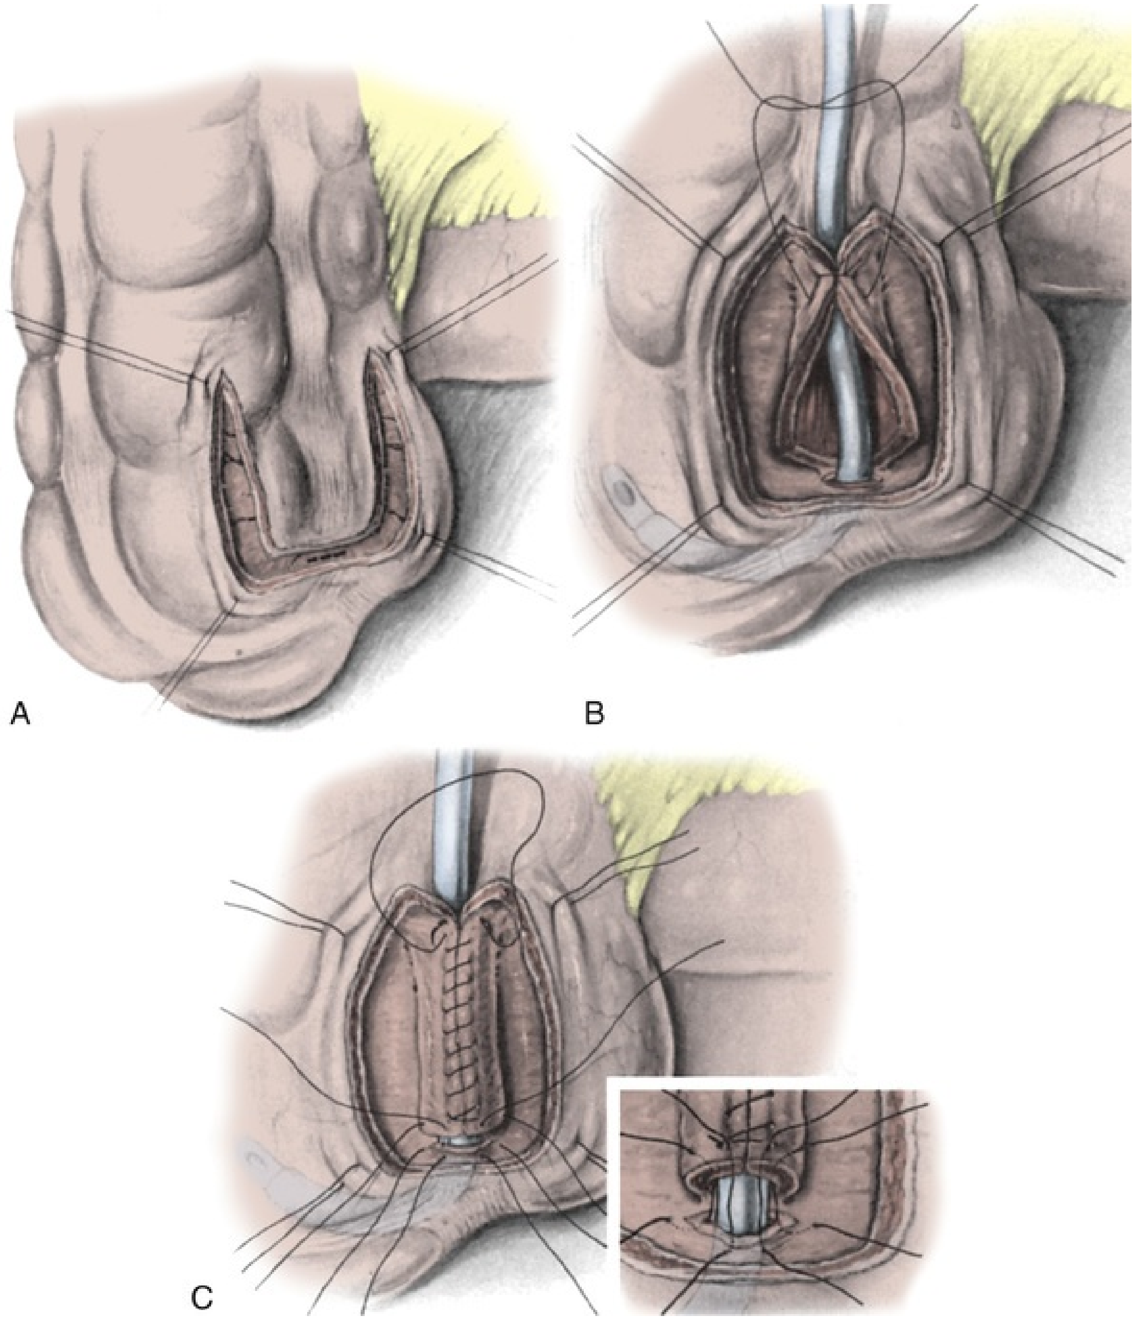

FIG. 140.8 (A to C) A 3- to 5-cm seromuscular tube denuded of mucosa and lined by serosa is fashioned for tunneled reimplantation. The tube is rolled over an 18-Fr Foley catheter. A mucosal window is opened at the base of the U, and the tube sutured to the mucosa with interrupted sutures. (From Lampel A, Hohenfellner M, Schultz-Lampel D, et al.: In situ tunneled bowel flap tubes: 2 new techniques of a continent outlet for Mainz pouch cutaneous diversion. *J Urol* 153:308–315, 1995.)

Another novel Mitrofanoff continence mechanism was described by Montie (1997), who conceived of a procedure in which a 2- to 3-cm segment of terminal ileum is isolated on its blood supply (Fig. 140.9A). The width of the segment was chosen to correspond to the circumference of the tube to be created. Once isolated, the segment is opened near one of its mesenteric junctions to create a longitudinal reconfiguration (Figs. 140.9B and C). The tube is then closed with a running 3-0 absorbable suture (Fig. 140.9D). It can now be used for a Mitrofanoff implant. When longer tubes are necessary, two adjacent segments can be isolated, reconfigured, and joined together (Figs. 140.9E and F). Although the technique was originally described in dogs, Montie (1997) has used it in humans without complication. Montie (1997) reported on a high rate of stomal stenosis in dogs, but this may have been secondary to infrequent catheterizations. Stomal stenosis has not occurred in our limited series of patients. Other groups have used tapered ileum to create a tunneled access into the right colon (Fig. 140.10) (Hampel et al., 1995; Woodhouse and MacNeily, 1994). Using tapered ileum for this purpose has the advantage of a blood supply independent of the reservoir and no length restrictions while having the disadvantage of further limiting intestinal absorptive surface.

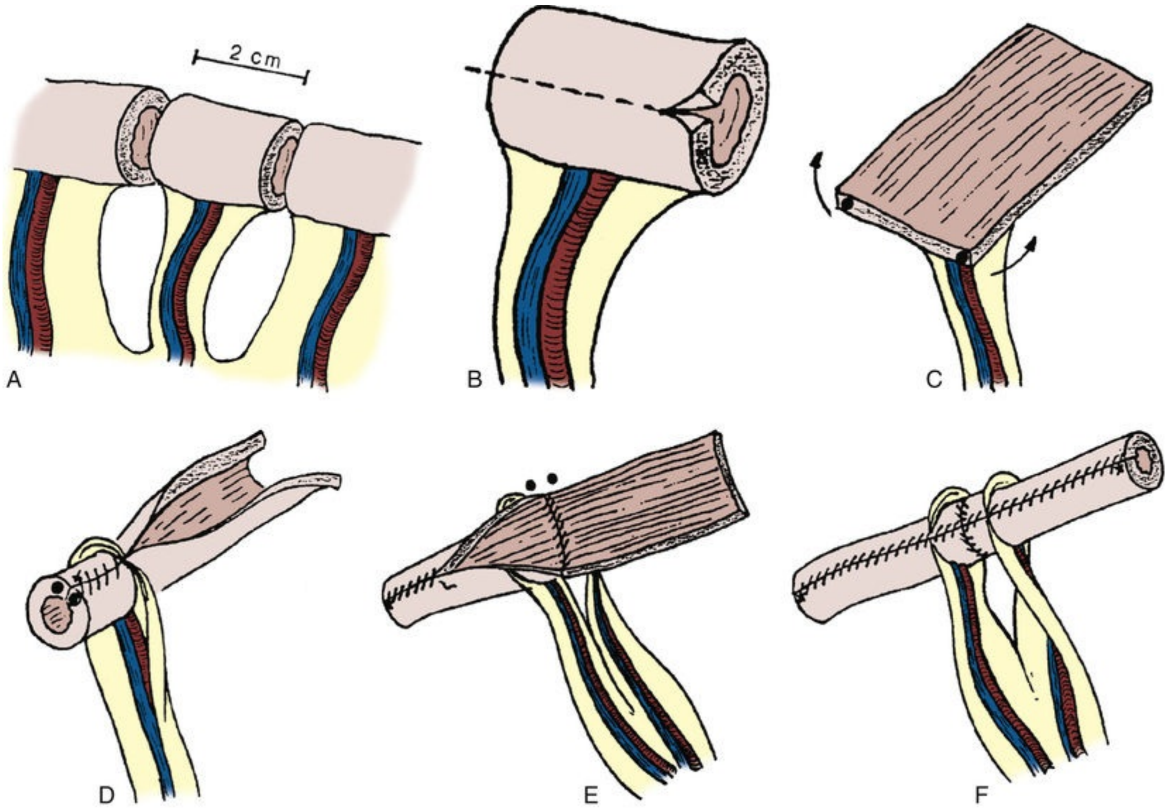

FIG. 140.9 (A) A 2- to 3-cm segment of terminal ileum is isolated on its own blood supply. (B and C) The tubular segment is opened approximately

one-fourth of the way up one side. This results in a well-vascularized rectangular plate. (D) The rectangular tube is now closed over a catheter with a running absorbable suture. (E and F) Two adjacent segments can be joined together to create one long tube. (From Monti PR, Lara RC, Dutra MA, et al.: New techniques for construction of efferent conduits based on the Mitrofanoff principle. *Urology* 49:112–115, 1997.)

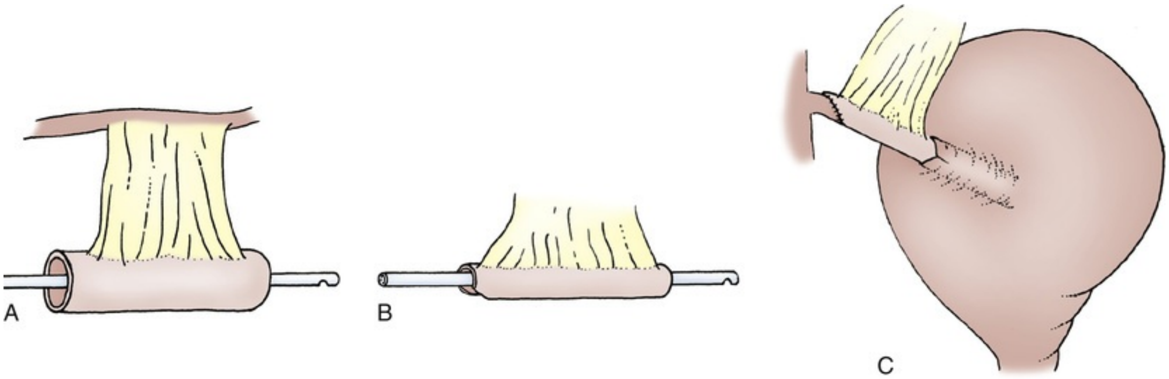

FIG. 140.10 (A to C) Woodhouse tapered ileum. (From Woodhouse CR, MacNeily AE: The Mitrofanoff principle: expanding upon a versatile technique. *Br J Urol* 74:447–453, 1994.)

Wiesner et al. (2007) compared their long-term results in 458 patients who underwent Mainz I pouch construction. The anastomosis was made using a submucosal tunnel in 809 renal-ureteric units and using a serosa-lined extramural tunnel in 74 units. At 17 months postoperatively they found a significantly higher occurrence of anastomotic obstruction in the submucosal tunnel group compared with the extramural group (7.3% vs. 4.1%, respectively). They found a much higher rate of obstruction in patients with previously dilated upper tracts (14%) or with a history of neurogenic bladder (17%). No significant deterioration of the upper tracts was identified.

In another comparison of patients with a Mainz I pouch, Wiesner et al. (2006) reported on 800 patients with almost 8 years of follow-up. Overall continence was approximately 93%. Stomal stenosis occurred in 23.5% of patients with a submucosally embedded in situ appendix, whereas stenosis was reported in 15.3% of patients with an intussuscepted ileal nipple valve. Rates of calculi formation were the reverse: 10.8% incidence in patients with an ileal nipple valve but in only 5.6% of patients with an appendix stoma. Ischemic degeneration of the continence mechanism occurred almost three times more often in the appendiceal group.

Right Colon Pouches With Intussuscepted Terminal Ileum

Additional pouches using nipple valve technology for the continence mechanism include those right colon pouches in which intussusception of the terminal ileum and ileocecal valve is employed. These are variations on the continent cecal reservoir initially described by Mansson (1987) that employ an intact cecal segment. These three pouches are the UCLA pouch (Raz, personal communication, 1989), the Duke pouch (Webster and King, 1987), and Le Bag (Light and Scardino, 1986). These surgeries differ from one another by only a few features, mainly related to the technique employed for stabilizing the nipple valve. Unless the appendix is being used as a continence mechanism, appendectomy should be performed in all cases because an in situ appendix would serve as a nidus for infection and abscess formation.

These operations are described in detail in the prior edition of this text. Since that edition was published, no new modifications to these procedures have been reported, and they are not further described here. The reader is referred to the prior edition of this text for an in-depth description of these operations.

Indiana Pouch

The concept of using the buttressed ileocecal valve as a dependable continence mechanism that can withstand the trauma of intermittent catheterization was first reported by Rowland et al. (1987) **from Indiana University.** This operation, which involved the partial spatulation of the cecal segment and attachment of an ileal patch, represented major contributions to the original ileocecal reservoir as described by Gilchrist et al. (1950), in which the intact bowel reservoir was employed and no attempt was made to strengthen the ileocecal valve. Originally, strengthening the ileocecal valve consisted of making a double row of imbricating sutures to the entire ileal segment (Rowland et al., 1985, 1987). It soon became apparent that this was necessary only in the region of the ileocecal valve. “Neourethral” pressure profiles showed that the continence zone was confined to the region of the reconfigured ileocecal valve (Bejany and Politano, 1988). The remaining “neourethra” could be tapered and brought through an abdominal or perineal stoma. At Indiana University, as well as other institutions, it became clear that the concept of marsupializing only a portion of the ascending colon segment left enough peristaltic integrity in the cecal region to generate pressures sufficiently high to overcome the continence mechanism in some patients. A number of groups contributed to the concept of using the entire right colon or more, marsupializing the entire structure and refashioning it in a Heineke-Mikulicz configuration (Bejany and Politano, 1988; Benson et al., 1988; Lockhart, 1987; Rowland, personal communication, 1989). These variations have been entitled the Florida pouch (Lockhart, 1987) and the University of Miami pouch (Bejany and Politano, 1988). However, they represent relatively minor variations on the theme of the Indiana pouch.

Procedure.

The Indiana pouch in its present form involves isolating a segment of terminal ileum approximately 10 cm in length along with the entire right colon to the junction of the right and middle colic artery blood supplies (Fig. 140.11A). After bowel continuity is reestablished, appendectomy is performed and the appendiceal fat pad obscuring the inferior margin of the ileocecal junction is removed by cautery (Fig. 140.11B). The entire right colon is opened along its antimesenteric border, and ureteral-taenial implants are fashioned (Fig. 140.11C). The ileocecal junction is buttressed according to various reported techniques. With nonabsorbable sutures, interrupted Lembert sutures are taken over a distance of 3 to 4 cm in two rows for the double imbrication of the ileocecal valve as described at Indiana University (Fig. 140.11D). The second row of sutures should attempt to bring the opposite mesenteric edges of ileum together, usually over a 12- to 14-Fr catheter. These two rows of sutures should be placed approximately 8 mm from one another, and the initial suture in each row may be taken in a purse-string fashion around the cecal margin as well. Alternatively, the University of Miami group suggests placing purse-string sutures in the same ileal region (Bejany and Politano, 1988). Finally, the Tampa group suggests placement of apposing Lembert sutures on each side of the terminal ileum (Fig. 140.11E). The remaining ileum can be tapered over the catheter and excess ileum removed with a stapling technique (Fig. 140.11F).

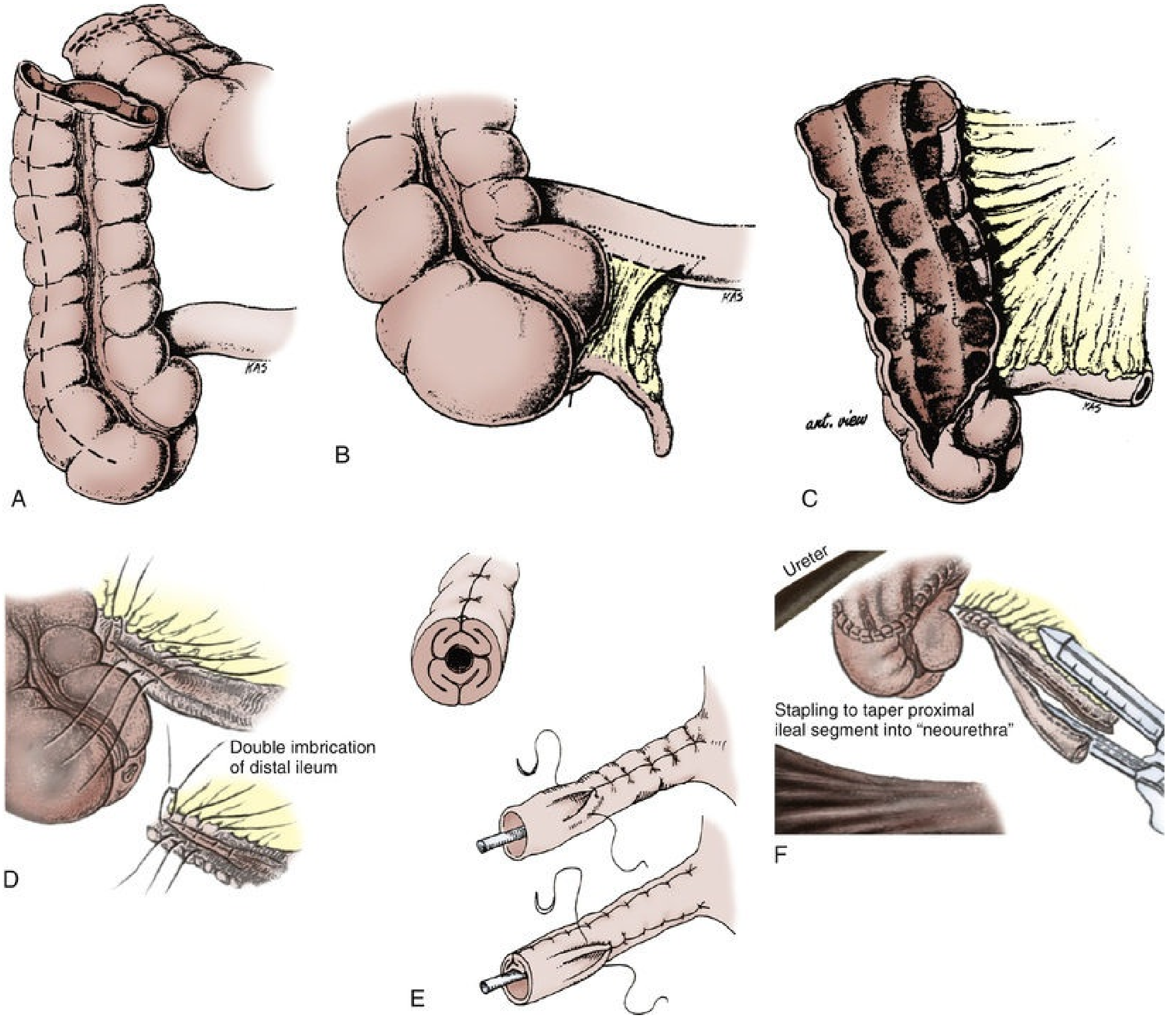

FIG. 140.11 (A) A segment of terminal ileum approximately 10 cm in length along with the entire right colon is isolated. (B) Appendectomy is performed, and the appendiceal fat pad obscuring the inferior margin of the ileocecal junction is removed by cautery. (C) The entire right colon is opened along its antimesenteric border. (D) Interrupted Lembert sutures are taken over a short distance (3 to 4 cm) in two rows for the double imbrication of the ileocecal valve as described at Indiana. (E) Application of apposing Lembert sutures on each side of the terminal ileum. (F) Excess ileum can be tapered by stapling technique. (A to C, From Benson MC, Sawczuk IS, Hensle TW, et al. Modified Indiana University continent diversion. *Curr Surg Tech Urol* 1:1–8, 1988. D and F, From Olsson CA: *Contemp Urol* 62–68, September 1989. E, From Lockhart J: Remodeled right colon: an alternative urinary reservoir. *J Urol* 138:730–734, 1987.)

It is important to carry out the imbrication while the cecal reservoir is still open (Rowland, 1996) so that the gradual closure of the ileocecal valve can be closely observed. The pouch is then closed in a Heineke-Mikulicz configuration with a running absorbable suture. Ureteral stents and a suprapubic tube are taken through a stab wound in the pouch and led through the right lower abdominal quadrant. The pouch is rotated so as to bring the ileal neourethra as close as possible to the selected stoma site. A fingerbreadth-wide skin button is transected along with a similar button from the anterior and posterior fascia. The ileal neourethra is advanced between bundles of the rectus muscle through the stoma and excess ileum is transected. The ileal edges are sewn to skin with interrupted sutures so as to create a flush stoma.

In addition to the differences in the technique of ileocecal valve imbrication, the University of Miami and the Florida pouches differ in the amount of colon used. The entire ascending colon and the right third or half of the transverse colon is isolated along with 10 to 12 cm of ileum. The entire upper extremity of the large bowel is mobilized laterally in the fashion of an inverted U (Fig. 140.12A). The medial limbs of the U are sutured to each other after the bowel has been spatulated (Fig. 140.12B). The bowel plate is then closed side to side (Fig. 140.12C). This inverted-U closure, however, is exactly the same as a Heineke-Mikulicz reconfiguration.

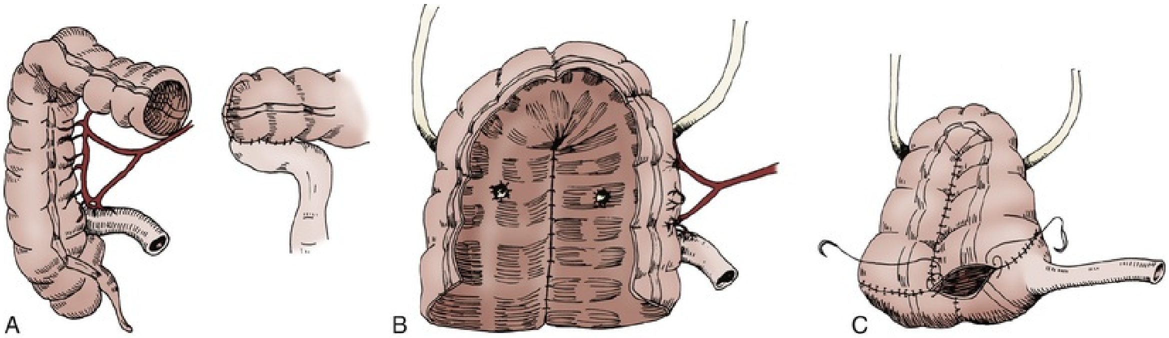

FIG. 140.12 (A) The entire ascending colon and the right third or half of the transverse colon is isolated along with 10 to 12 cm of ileum. (B) The entire upper extremity of the large bowel is mobilized laterally in the fashion of an inverted U. The medial limbs of the U are sutured after the bowel has been spatulated. (C) The bowel plate is then closed side to side. (From Lockhart J: Remodeled right colon: an alternative urinary reservoir. *J Urol* 138:730–734, 1987.)

There have been subsequent modifications to the Indiana reservoir that allow for more rapid construction and a lower complication rate (Rowland, 1996). The modifications incorporate the use of metal staples to create the efferent limb and absorbable staples to fashion the reservoir. The concept of using a metal GIA stapler to fashion the efferent limb was first introduced by Bejany and Politano (1988). Carroll and Presti (1992) reported on the urodynamic features of the stapled and plicated terminal ileum and found that the stapled limb performed equally well and was easier to construct. The use of absorbable staples to create this and other types of reservoirs is described later in the chapter.

Postoperative Care and Comments.

The postoperative care of the patient with an Indiana pouch and its variants is not substantially different from that used in patients with other right colon catheterizable diversions. In early reports, Rowland recommended discharging the patient with the suprapubic tube in place until readmission to the hospital 3 weeks later for tube removal and instruction in self-catheterization. In the current medical climate, which places a premium on outpatient procedures, tube removal and catheterization instruction are now ambulatory procedures at most institutions, including Indiana University (Bihrle, 1997).

Average pouch capacities of 400 to 500 mL have been reported by the Indiana group (Rowland et al., 1987). Combining the partially and totally spatulated bowel procedures, this group reports a reoperation rate of 26%. Overall continence rates of 93% have been achieved. Very elegant urodynamic studies were conducted in Indiana pouch variants by Carroll et al. (1989). They found only 86% of patients totally continent in a small series. However, their pouch capacities exceeded 650 mL, and peak contractions of 47 cm H_2O were recorded at capacity.

The last 81 patients operated on by Rowland underwent construction of a stapled efferent limb, and in the last 20 the reservoir was created with absorbable staples (Rowland, 1996). **The results in this group of patients were extremely favorable. Early pouch-related complications occurred in only 3 patients (3.7%).** Two patients experienced a pouch leak that was managed conservatively, and 1 patient required open revision of the efferent limb because of the difficulty with catheterization. Early complications not directly attributable to the pouch occurred in 7 patients (8.6%). Transient small bowel obstruction was the most common complication, occurring in 4 patients (4.9%). One patient developed a superficial wound infection, and 1 patient developed an abdominal abscess requiring surgery (1.2%). Late complications associated with the reservoir occurred in 23 patients (28.4%). Incontinence occurred in 6 patients (7.4%): in 5 patients it occurred secondary to high pouch pressures, and in the remaining patient it was caused by failure of the efferent limb. One of the former and the latter patient underwent reoperation. Three patients (3.7%) developed stomal stenosis, and 3 had parastomal hernias; all 6 underwent surgery. Pouch stones occurred in 3 patients: 1 underwent open removal, and 2 had endoscopic extraction. Acute pyelonephritis was seen in 4 patients (4.9%). The most common late complication not related to the pouch was small bowel obstruction; this was seen in 6 patients and was managed conservatively in 5. In summary, the early reoperation rate was 2.5% and the late reoperation rate 14.8%. **At 1 year, daytime and nighttime dry intervals of 4 hours or longer were achieved in 98% of patients.** Eighty-four percent of patients stated that they slept through the night without the need to awake for catheterization. Similarly, excellent results in the last 150 patients, 50 with at least 2½-year follow-up, were reported by Bihrle (1997).

The Florida pouch has been performed in 190 patients (Helal et al., 1993; Webster et al., 2003). In 165 patients and 326 ureters, no attempt was made to create a tunneled reimplantation. This approach was adopted because of the high incidence of ureteral obstruction encountered in the first 30 ureters that were tunneled into a Florida pouch (43 patients, 13.3%). In the last 165 patients, 16 of 326 ureters (4.9%) developed primary obstruction and were treated by percutaneous balloon dilation, nephrectomy, or observation. Although no attempt was made to create an antirefluxing anastomosis, only 7.1% of the ureters implanted demonstrated reflux. All patients are being followed conservatively, and no renal deterioration has been demonstrated. In the initial 100 patients, a 7.2% reoperation rate was reported (Lockhart, 1987). Although hyperchloremia was noted in 70% of patients, only 4 patients (including those who had preexisting renal disease) required treatment. Reservoir capacities ranged from 400 to 1200 mL, and maximal reservoir pressures at capacity ranged from 18 to 55 cm H_2O (Lockhart, 1987). The reason why these authors experienced such a high incidence of ureteral obstruction with nontunneled and tunneled ureteral colonic anastomoses is not clear. It is also surprising that only 23 of 326 ureters that were anastomosed end to side had reflux.

The University of Miami group has reported on its results in 75 patients. Early complications occurred in 19 patients (25%). Sixteen patients (21%) experienced late complications. The success rate of the ureterocolonic anastomosis was 90%, and total continence occurred in 98.6% of patients. Average pouch capacities were 750 mL or higher, and end filling pressures of 20 cm H_2O were reported. No patient required alkali therapy.

The Indiana pouch remains one of the most reliable of all catheterizable reservoirs. It is among the easiest to construct, and it has very low rates of short-term and intermediate-term (<2 years) complications (Navon et al., 1995; Rowland and Kropp, 1994). **However, there is evidence that the rate of long-term complications, mainly involving the efferent limb in a modified version of the Indiana Pouch, may be higher** (Holmes et al., 2002).

In our experience, the most common late complication is the development of stones within the pouch. Although most are asymptomatic, they can result in a higher incidence of “pouchitis.” The most common cause is insufficient pouch irrigation resulting in calcification of retained mucus. Pouch stones should not be treated with lithotripsy because it is not feasible to eliminate all fragments. These fragments will serve as a nidus for further stone formation. The best approaches are either a small McBurney incision with direct extraction or a percutaneous approach to the reservoir with placement of the stone(s) into a specimen bag.

Penn Pouch

The Penn pouch was the first continent diversion employing the Mitrofanoff (1980) principle, in which the appendix served as the continence mechanism. As mentioned earlier, this operation enjoys the singular feature of affording a catheterizable continent diversion that can be performed using techniques already present in the urologic armamentarium.

Procedure.

Two techniques of appendiceal continence mechanisms have been reported. Mitrofanoff reported excising the appendix with a button of cecum and reversing it on itself before tunneled reimplantation (Duckett and Snyder, 1986; Mitrofanoff, 1980). Alternatively, Riedmiller et al. (1990) left the appendix attached to the cecum and buried it into the adjacent taenia by rolling it back onto itself. A wide tunnel is created in the taenia extending 5 to 6 cm from the base of the appendix (Fig. 140.13). Windows are created in the mesoappendix between blood vessels. The appendix is folded cephalad into the tunnel, and seromuscular sutures are placed through the mesoappendix windows to complete the tunneling. The tip of the appendix is amputated and brought to the selected stoma site.

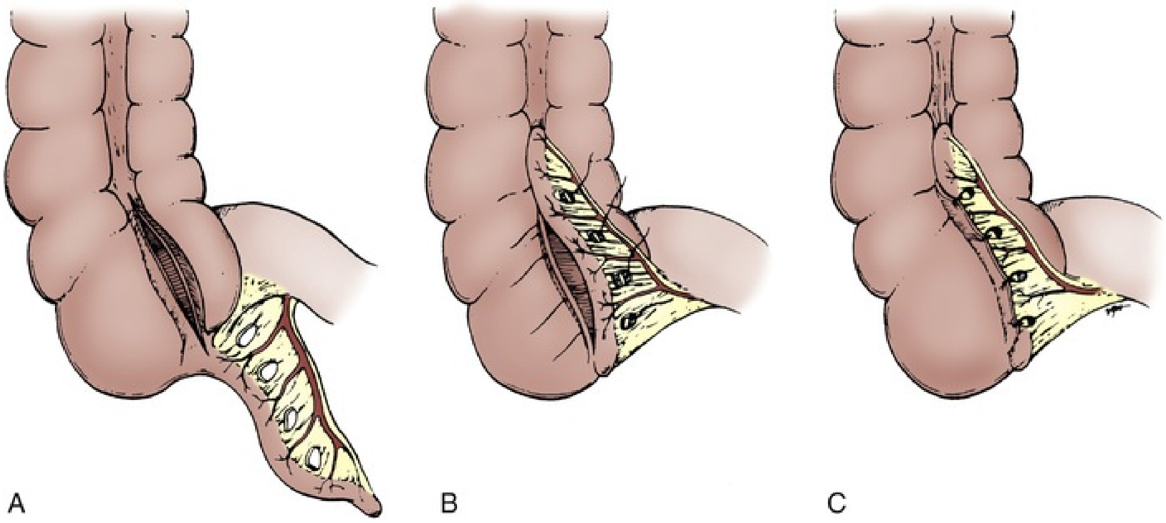

FIG. 140.13 (A) The appendix is left attached to the cecum and buried into the adjacent cecal taenia by rolling it back onto itself. A wide tunnel is created that extends 5 to 6 cm from the base of the appendix. Windows are created in the mesoappendix between blood vessels. The appendix is folded cephalad into the tunnel (B), and seromuscular sutures are placed through the mesoappendix (C).

As described by Duckett and Snyder (1986), an ileocecal pouch is created by isolating a segment of cecum up to the junction of the ileocolic and middle colic blood supplies along with a similar length of terminal ileum. These two structures are marsupialized on the antimesenteric borders and sutured to one another in the form of a neotubularized pouch. The superior margin of the pouch is sutured in a transverse fashion (all sutures being of absorbable material). A button of cecum surrounding the origin of the appendix is circumcised, and the resulting cecal aperture is closed with running absorbable suture. The mesentery of the appendix is dissected carefully from the base of the cecum, thereby preserving its blood supply. The appendix is then reversed on itself so that the cecal button can reach the anterior abdominal wall and the tail of the appendix can be directed to the taenia of the colon (Fig. 140.14). The appendiceal tip is obliquely transected and may be spatulated; then a tunneled appendiceal-taenial implantation is carried out. If additional appendiceal length is required, the variation proposed by Burns and Mitchell (1990) of creating a tube from the base of the cecum can be employed (see Fig. 140.3). Instead of simple removal of the appendix with a button of cecum before preparing it for tunneling, the entire base of the cecum leading to the appendix can be resected in continuity with the appendix by the application of the GIA stapler. We have found it helpful to spatulate the distal tip of the appendix until it accommodates a catheter at least

12 to 14 Fr in diameter.

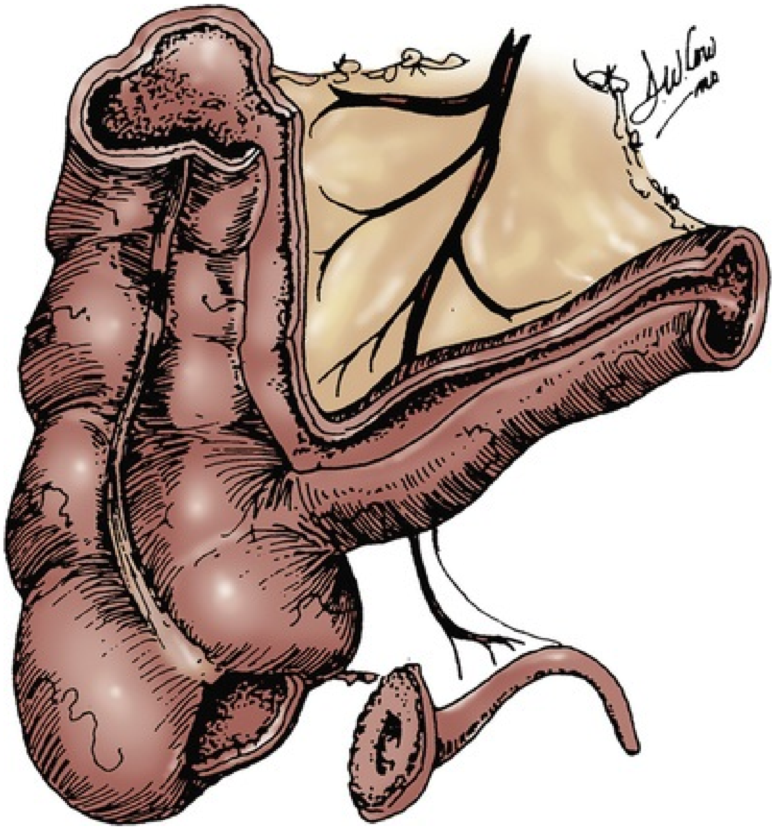

FIG. 140.14 A segment of cecum up to the junction of the ileocolic and middle colic blood supplies along with a similar length of terminal ileum is isolated and marsupialized on the antimesenteric borders. A button of cecum surrounding the origin of the appendix is circumcised. The mesentery of the appendix is dissected carefully from the base of the cecum, preserving its blood supply. (From Duckett JW, Snyder HM 3rd: The Mitrofanoff principle in continent urinary reservoirs. *Semin Urol* 5:55–62, 1987.)

Postoperative Care and Comments.

Although not shown in Duckett's surgical drawings, we suggest that a large-bore suprapubic tube be used to drain the pouch in the early postoperative interval. The size of the catheter admitted by the appendiceal stump is insufficient to allow for the passage of ureteral stents along with the 12- to 14-Fr catheter. In addition, safe irrigation of mucous debris is best managed by a larger-bore catheter.

Many groups have used the Mitrofanoff principle because of the simplicity and reliability of the continence mechanism (Bissada, 1993; Burger et al., 1992; Hampel et al., 1995; Sumfest et al., 1993; Woodhouse and MacNeily, 1994). Woodhouse and MacNeily (1994) reported on a series of 100 patients who underwent surgery from 1985 to 1993. Seven different catheterizable conduits into six different types of reservoir were used. Although these researchers found the Mitrofanoff principle to be versatile and associated with a high success rate (91% continence), the reoperation rate for tube complications was 33%.

Sumfest et al. (1993) affirmed the use of the appendix as the Mitrofanoff segment of choice. They reported a continence rate of 96%. In their hands, late complications included difficulty with catheterization in 10.6% and stomal stenosis in 19.1%.

Urodynamic properties and pouch capacities will be a function of the reservoir constructed. Most often, the appendix is used in situ (Burger et al., 1992), and the right colon, either alone or with associated terminal ileum (Mainz), serves as the reservoir. We have used the in situ appendix with a detubularized right colon reservoir and the native ileocecal valve as an antireflux mechanism (refluxing ureters implanted end to side into terminal ileum). In our hands this has resulted in an excellent success rate with no upper tract problems. The adequacy of the ileocecal valve as an antireflux mechanism was also reported by Alcini et al. (1994). In their series, however, the reservoir was not always detubularized and, as expected, upper tract complications ensued because of high reservoir pressures. This procedure is uniquely capable of affording continent cutaneous diversion to the patient with short ureters because the terminal ileum can be left long enough to reach high into the retroperitoneum.

Gastric Pouches

Pioneering animal experimentation demonstrated the feasibility of employing stomach as a bladder patch or urinary reservoir (Leong, 1978; Rudick et al., 1977; Sinaiko, 1956). **The use of the stomach to create a urinary reservoir has theoretic as well as real advantages** (Adams et al., 1988). **First, electrolyte reabsorption would be greatly diminished by use of this bowel segment in the reservoir. This would potentially make the stomach the selected reservoir for individuals with preexisting metabolic acidosis or renal insufficiency. Hyperchloremic acidosis would not be an anticipated problem; in fact, in addition to presenting a barrier against the absorption of chloride and ammonium, the gastric mucosa secretes chloride ions** (Piser et al., 1987). **Furthermore, in patients in whom shortening of the bowel may**

be expected to lead to some degree of malabsorption, the use of stomach is an attractive alternative. The acid pH of the urine may also reduce the risk of bacterial colonization. Finally, when the entire lower bowel has been irradiated, stomach tissue may provide healthy nonirradiated tissue for use in performing continent diversion. Given these theoretic advantages, a number of groups have initiated trials with gastric pouches and composite reservoirs in pediatric (Adams et al., 1988) and adult (Austin et al., 1997; Lockhart et al., 1993) populations.

Procedure.

A wedge-shaped segment of stomach with maximal width of 7 to 10 cm is fashioned from the greater curvature. Care is taken not to extend the wedge through to the lesser curvature to preserve vagal innervation and normal gastric emptying. The left gastroepiploic artery is preferentially used as the blood supply for the isolated gastric wedge, dividing the short gastric vessels from the more proximal artery up to the gastric fundus. Alternatively, if there is a problem with the left artery, the right gastroepiploic vessel may be employed, dividing the short gastric vessels to the level of the pylorus (Figs. 140.15A and B). The stomach is then closed according to the surgeon's preference. Neither gastroduodenostomy nor gastrojejunostomy is mandatory unless the antrum of the stomach has been used. The isolated wedge is refashioned into nearly a sphere by folding it back on itself and suturing the edges together with running absorbable material. Before pouch closure, one ureter is tunneled into the reservoir according to the surgeon's preferred antireflux technique. Contralaterally, proximal transureteroureterostomy is performed. The contralateral distal ureter is used to create the continence mechanism. The distal ureter is tunneled into the reservoir in a fashion similar to an appendiceal implant. The free portion of the ureter can then be brought to the skin or to the introitus (or urethral stump in males) to serve as a catheterization portal (Fig. 140.15C). Alternatively, the wedge of stomach can be incorporated into a reservoir composed of detubularized ileum (Lockhart et al., 1993). In this procedure, an 11-cm segment of stomach is isolated on the right gastroepiploic blood supply (Fig. 140.16A). A 22-cm segment of ileum is then isolated, opened along its antimesenteric border, and refashioned in a U shape (Fig. 140.16B). The edges of the stomach are then sutured to edges of the ileum with a running absorbable suture of 2-0 PGA. This completes the reservoir. The ureters are tunneled into the stomach, and a Mitrofanoff continence mechanism is created according to the preference of the surgeon. For example, the group from the University of South Florida employs a tapered segment of ileum (Fig. 140.16C).

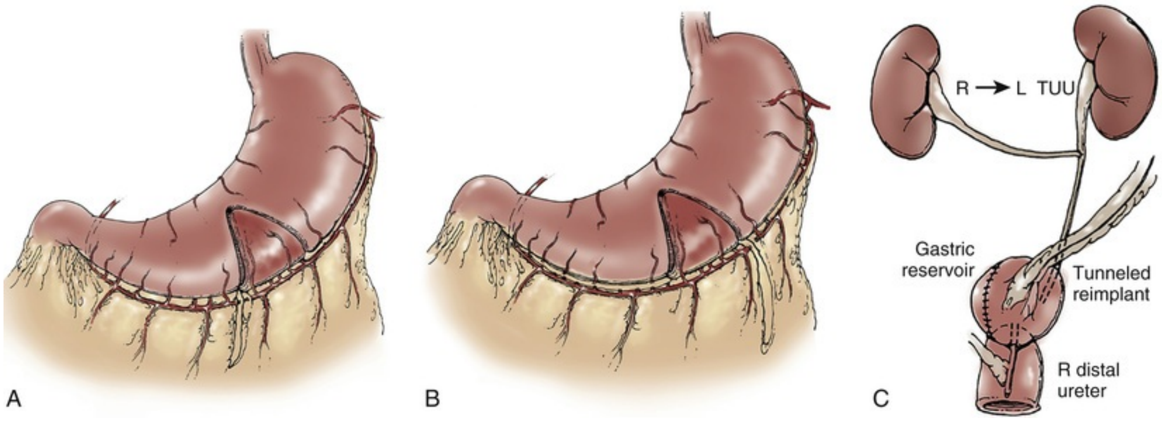

FIG. 140.15 (A and B) A wedge-shaped segment of stomach whose greatest width is 7 to 10 cm is fashioned from the greater curvature. The left gastroepiploic artery is preferentially used as the blood supply for the isolated gastric wedge by dividing the short gastric vessels up to the gastric fundus. Alternatively, if there is a problem with the left artery, the right gastroepiploic vessel may be employed. (C) The isolated wedge is refashioned into nearly a sphere by folding it back on itself and suturing the edges together with running absorbable material. One ureter is tunneled into the reservoir. A proximal transureteroureterostomy is performed. The ipsilateral distal ureter is tunneled into the reservoir with its distal extent brought to the introitus to serve as a catheterization portal. *R → L TUU,* Right-to-left transureteroureterostomy. (From Adams MC, Mitchell ME, Rink RC: Gastrocystoplasty: an alternative solution to the problem of urological reconstruction in the severely compromised patient. *J Urol* 140:1152–1156, 1988.)

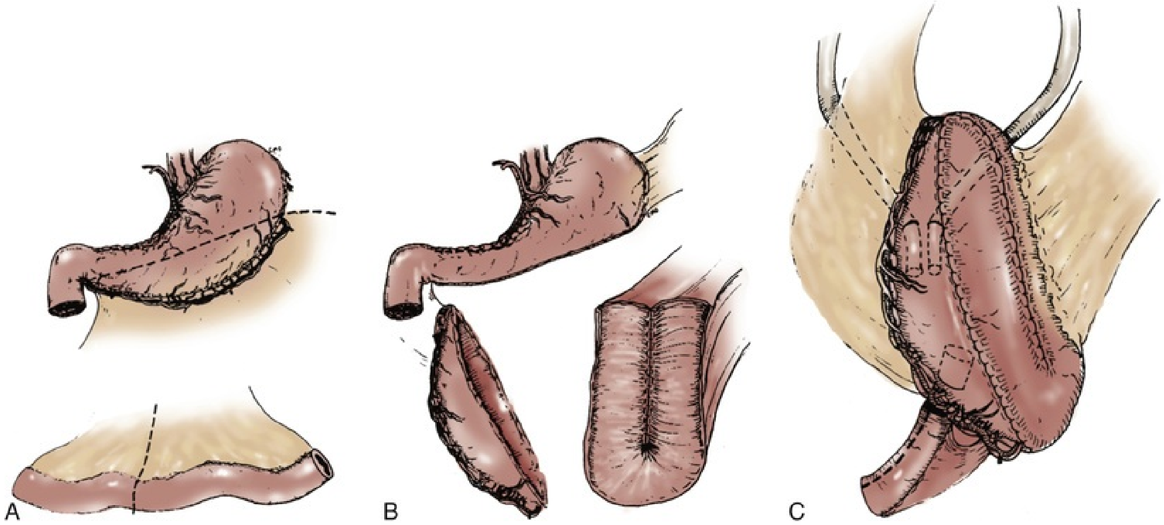

FIG. 140.16 (A) An 11-cm segment of stomach is isolated on the right gastroepiploic blood supply using a GIA-90 stapler. Usually two staplers are required. (B) A 22-cm segment of ileum is then isolated, opened along its antimesenteric border, and refashioned in a U shape. (C) The edges of the stomach are then sutured to edges of the ileum with a running absorbable suture of 2-0 polyglycolic acid. This completes the reservoir. The ureters are tunneled into the stomach, and a Mitrofanoff continence mechanism is created with a tapered segment of ileum. (From Lockhart JL, Davies R, Cox C, et al.: The gastroileal pouch: an alternative continent urinary reservoir for patients with short bowel, acidosis and/or extensive pelvic radiation. *J Urol* 150:46–51, 1993.)

Postoperative Care and Comments.

Adams et al. (1988) reported mean pouch capacities of 245 mL and end filling pressures averaging 35 cm H_2O in a small patient sample. Combining their experience of gastric continent diversion and gastrocystoplasty, they reported minimal mucus production: only 3 of 13 patients required any irrigations, and the majority maintained sterile urine. Urine pH ranged from 4 to 7, but no introital ulceration from acid urine was reported. Three patients had minor elevations of serum gastrin, and none of the continent diversions required reoperation. Leong (1978) used similar concepts in gastric pouch construction and alluded to the creation of a voiding pouch created from stomach as well.

The construction of reservoirs entirely from stomach has not seen widespread acceptance. Rather, there has been greater use of stomach segments either for bladder augmentation or as a portion of a reservoir (composite) either alone or with an in situ catheterizable tube fashioned from a portion of the stomach (Carr and Mitchell, 1996; Gosalbez et al., 1994).

Gosalbez et al. (1994) reported on 15 patients who received a gastric tube as part of a composite gastric patch. Complications associated with the gastric patch and in situ tube included one each of early traumatic perforation of the tube, distal tube stenosis, and mucosal redundancy. Two of these patients required reoperation. Peristomal skin irritation from acid secretion occurred in 2 patients but was not considered severe. This is a more frequent complication in other reports and has resulted in skin breakdown in some instances.

Over a 10-year period from January 1985 to June 1995, Carr and Mitchell (1996) reported on the use of stomach in 12 patients. Seven had urinary reservoirs totally constructed from stomach, whereas 5 had composite reservoirs. They reported continence in all patients but that the continence mechanisms often required revision. Average bladder capacity was 309 mL, and average compliance was 12.9 mL/cm H_2O. When stomach is used as a bladder augment or as a portion of a neobladder, a dysuria and hematuria syndrome has been reported (Nguyen et al., 1993).

Austin et al. (1997) reported on nine adult patients with a mean follow-up of 54 months who underwent construction of a continent composite reservoir that was gastroileal in 7 and gastrocolonic in 2. All 9 patients had either preexisting metabolic acidosis or a short bowel syndrome. All 9 patients achieved electrolyte neutrality, and postoperative serum pH was significantly improved ($P < .01$). Three patients had a short-term serum gastrin elevation; the level returned to normal during follow-up. One patient developed skin ulceration at the stoma site.

The use of stomach has particular appeal in the pediatric population, in which the stomach's unique acid-base properties can be used not only to reconstruct but also to help correct the metabolic problems that are often associated with the need for pediatric urinary reconstruction (Carr and Mitchell, 1996)**. Although experience with use of the stomach remains small, its various unique intrinsic properties as a reservoir suggest that its use will continue in selected clinical situations.**

Quality-of-Life Assessments

Few well-designed, prospectively conducted studies using validated instruments exist to assess quality of life after various forms of urinary diversion and even fewer that include the less common continent cutaneous urinary diversions. Multiple international studies have suggested an improved psychosocial adjustment of the patient undergoing continent urinary and fecal diversion in general compared with those patients with diversions requiring collecting appliances (Bjerre et al., 1995; Filipas et al., 1997; Hart et al., 1999; McGuire et al., 2000; Salter, 1992a, 1992b). Although this may indeed be true, as exemplified by individuals with a conduit who desire conversion to a continent procedure, it is also true that many, if not most patients, adjust well to wearing external appliances. The sense of body image is a remarkably personal and subjective parameter that varies greatly from patient to patient. In general, body image and quality of life after a conduit procedure appear to remain good and may not be significantly different than after continent diversions (Gerharz et al., 2005; Hedgepeth et al., 2010; Somani et al., 2010). However, no randomized prospective trial has ever compared the quality of life after continent cutaneous diversion with that after either orthotopic continent diversion or incontinent urostomy, and there is no definitive conclusion that one form of urinary diversion is superior to any other (Porter and Penson, 2005). Of those studies performed, there appear to be common flaws in the study design and methods used that make any direct comparisons between continent and incontinent diversions difficult (Gerharz et al., 2005).

In general, most quality-of-life studies show similar results between patients undergoing ileal conduit and cutaneous continent diversion, with the latter being associated with improvements in stomal and urinary quality-of-life scores. In one of the few prospective studies to compare quality of life after continent cutaneous and ileal conduit diversion, Hardt et al. (2000) followed patients from the preoperative setting until 1 year after surgery. Using validated instruments tested for reliability, they found life satisfaction improved over time in patients with continent cutaneous diversion, whereas it worsened during the first year after ileal conduit construction. Using the Beck Depression Inventory and Profile of Mood States in adults, Boyd et al. (1987) found that patients choosing ileal conduit diversion had the lowest expectations of their quality of life. Boyd et al. found the highest overall satisfaction among patients undergoing conversion from ileal conduit to Kock cutaneous pouch diversion.

Mansson et al. (2002) found no difference in overall quality of life in men undergoing continent cutaneous diversion when compared with orthotopic neobladder using the Functional Assessment of Cancer Therapy (FACT)–Bladder and Hospital Anxiety and Depression Scale. In specific questions concerning intestinal, urinary, and sexual function, patients with cutaneous reservoirs experienced less difficulty with incontinence and emptied less frequently. Sexual function appeared better in patients undergoing orthotopic bladder substitution, likely because of urethral preservation. Large et al. (2010) used the validated FACT–Vanderbilt Cystectomy Index to compare quality-of-life measures in 92 women who underwent orthotopic neobladder compared with diversion with an Indiana pouch. With a median follow-up of at least 2 years, no significant difference was found in the physical, emotional, functional, or social measures of quality of life included in the instrument.

Variations in Operative Technique

Minimally Invasive Continent Cutaneous Diversion

With improvements in laparoscopic- and robotic-assisted techniques, radical cystectomy is now commonly performed in many centers using these minimally invasive techniques. Many of the centers performing minimally invasive radical cystectomy also perform orthotopic ileal neobladder procedures without converting to open techniques. There is significant literature concerning the potential benefits of this approach, but it is not covered here. In contrast, there are very few reports of continent cutaneous diversions performed using minimally invasive techniques. Given the surgical complexity of these types of diversions, the majority of centers perform continent cutaneous diversions via standard open techniques. Türk et al. (2001) reported on an initial series of five patients who underwent radical cystectomy with bilateral pelvic lymphadenectomy and continent urinary diversion with use of a rectosigmoid pouch performed with an intracorporeal laparoscopic technique. Bilateral stented antireflux ureteral reimplantation was used, and laparotomy was not performed. Operative time was 7.4 hours with minimal blood loss and a mean hospital stay of 10 days. No intraoperative or postoperative complications were encountered. Intermediate-term oncologic and functional outcomes were reportedly similar to those achieved with an open approach (DeGer et al., 2004). Goh et al. (2015) reported on a successful intracorporeal modified Indiana Pouch construction, lasting 3 hours, with no postoperative complications at 1 year. In the largest series available, Desai et al. (2017) reported on a series of 10 patients with at least 1 year of follow-up after intracorporeal Indiana Pouch diversion. Operative time lasted a mean of 3.5 hours (range 3–5 hours), and median hospital stay was 10 days (3–26 days). In terms of GI complications, 2 patients had a prolonged pouch leak managed conservatively. Two patients developed uretero-enteric anastomotic strictures. At 1-year follow-up, one patient had been undiverted because of noncompliance, and the remaining 9 were catheterizing without difficulty.

The complex nature of minimally invasive reconstructive surgery necessary in continent cutaneous diversion has limited these procedures to select centers. In addition, because of the prolonged time for return of postoperative bowel function, the benefits in hospital stay seen in other oncologic surgeries (e.g., laparoscopic nephrectomy) do not seem to exist when urinary diversion is performed.

Conduit Conversion to a Continent Reservoir

The major indication for conversion of a functioning conduit to a continent urinary reservoir is the patient's desire for improved quality of life. Pow-Sang et al. (1992) reported on conversion in 20 patients. Fifteen were converted from an ileal conduit and 1 each from a cecal conduit, ureterosigmoidostomy, cutaneous ureterostomy, sigmoid conduit, and a suprapubic tube. In 14 of the 20 patients the conduit was discarded or used only as a patch to a colonic reservoir. It was observed that renal units that were obstructed preoperatively were associated with a 71% failure rate. Metabolic acidosis was seen in 15 (75%) but was believed to be mild. Pouch-related complications are, in general, a function of the reconstruction selected, and complication rates should not necessarily be higher in this setting. However, patient selection is very important in determining appropriate candidates for conversion.

We prefer to use the conduit in some form whenever possible. This strategy was supported in a report on two patients by Oesterling and Gearhart (1990). The use of an existing bowel segment has the potential to diminish metabolic sequelae and may result in a lower complication rate. The form of continent reconstruction chosen will have to depend on intraoperative findings, and no one procedure is more amenable than another. Before conversion is undertaken, the patient should be fully evaluated for disease recurrence, renal functional status, urinary anatomy, hydronephrosis, intestinal length, and intestinal health.

Pahernik et al. (2004) have described the long-term outcomes of conversion of 39 patients from conduit diversion to Mainz I pouch diversion. With a mean follow-up of 102 months, the most common complications were stomal stenosis and pouch calculi. Long-term continence was achieved in 95% of patients.

Absorbable Stapling Techniques in Continent Urinary Diversion

The principle of bowel detubularization to increase reservoir capacity and diminish the effects of peristalsis is a fundamental principle of all contemporary continent urinary diversions. The process of detubularization and refashioning of the spatulated bowel segment consumes at least 1 hour of operating time and is by far the most time-consuming and tedious aspect of pouch construction. **The use of absorbable staples has substantially reduced the time required to fashion bowel reservoirs and has demonstrated short-term and long-term reliability with respect to reservoir integrity and volume.**

Bonney and Robinson (1990) first demonstrated the potential use of absorbable staplers to substitute for conventional suturing of bowel reservoirs. These authors used a bulky absorbable stapler (Polysorb staples in a TA Premium 55 stapler [US Surgical Corp., Norwalk, CT]) to construct an S-pouch configuration in a canine ileal urinary pouch model. Although the same stapler was used in humans by Bonney and Robinson in 1992 and by Cummings in 1995, its clinical use was never widely adopted because the bulky staple configuration destroyed a significant portion of the bowel diameter, particularly when applied to the small intestine. The fact that up to 20 costly staple cartridges were required to complete the closure of a bowel reservoir further reduced the potential benefits of absorbable pouch construction.

A 75-mm GIA instrument (PolyGIA, US Surgical Corp., Norwalk, CT) that incorporates substantially smaller absorbable staples was made available for clinical use in 1992. The stapler delivers four rows of absorbable polylactic acid and PGA blend copolymer staples, dividing the bowel between the second and third rows. Thus each staple line of the pouch has a double, staggered, stapled closure. This device has enabled both the refashioning and closure of bowel pouches to be performed with fewer staple applications and is strong and watertight. Finally, the width of bowel sacrificed with the new instrument is appreciably less than that with the older staple device. Several investigators have subsequently used the new “absorbable” GIA stapler to construct catheterizable pouches and neobladders (Montie et al., 1994, 1995; Olsson et al., 1993; Olsson and Kirsch, 1995). **However, the absorbable PolyGIA staples must not overlap because this will result in the failure of the staples to lock together. This is in direct contrast to metal staples, which are meant to overlap to create anastomotic integrity.** As a result of the need to prevent overlap of absorbable staples, the reservoir construction procedures must be varied when such staples are used, as described later.

Surgical Techniques

Right Colon Pouch

In 1993 Olsson et al. described a technique using the absorbable GIA staplers to fully detubularize and refashion large bowel. The technique of colon pouch construction described here incorporates the principles of bowel detubularization and refashioning using absorbable staplers in a simple “one-step” process.

The right colon and 10 cm of terminal ileum are mobilized by incising the peritoneum along the white line of Toldt and along the base of the mesentery and are isolated using metal GIA staplers (Fig. 140.17A). After bowel continuity has been restored with standard metal GIA and thoracoabdominal (TA) staplers, the distal staple line of the right colon is excised and the bowel lumen is irrigated to remove residual enteric contents. Using electrocautery, a small opening (2 cm) is created on the antimesenteric border of the cecum to fit the absorbable stapler. The distal open end of the colon is aligned with the cecostomy by folding the right colon on itself, as depicted in Fig. 140.17B. The limbs of the absorbable GIA stapler are inserted into the distal open end and into the cecostomy, and the stapler is fired along the antimesenteric line of the apposed folded bowel (Fig. 140.17C). It is necessary to evert the bowel to continue subsequent staple applications. This may be achieved by placing Babcock clamps on each side of the distal staple line (Fig. 140.17D). A small incision at the junction of each staple line is made to prevent overlap of the absorbable staple rows and to allow for the next staple application. Because of this incision, there is often a short unstapled area at the junction between each application of the stapler, requiring one or two simple figure-of-eight sutures of 2-0 absorbable material at each of these points. The last staple application traverses the apex of the fold of bowel. In adults, three to four applications of the stapling device have been required to construct the right colon pouch, whereas in children two or three staple applications suffice. The appearance of the nearly completed pouch is illustrated in Fig. 140.17E.

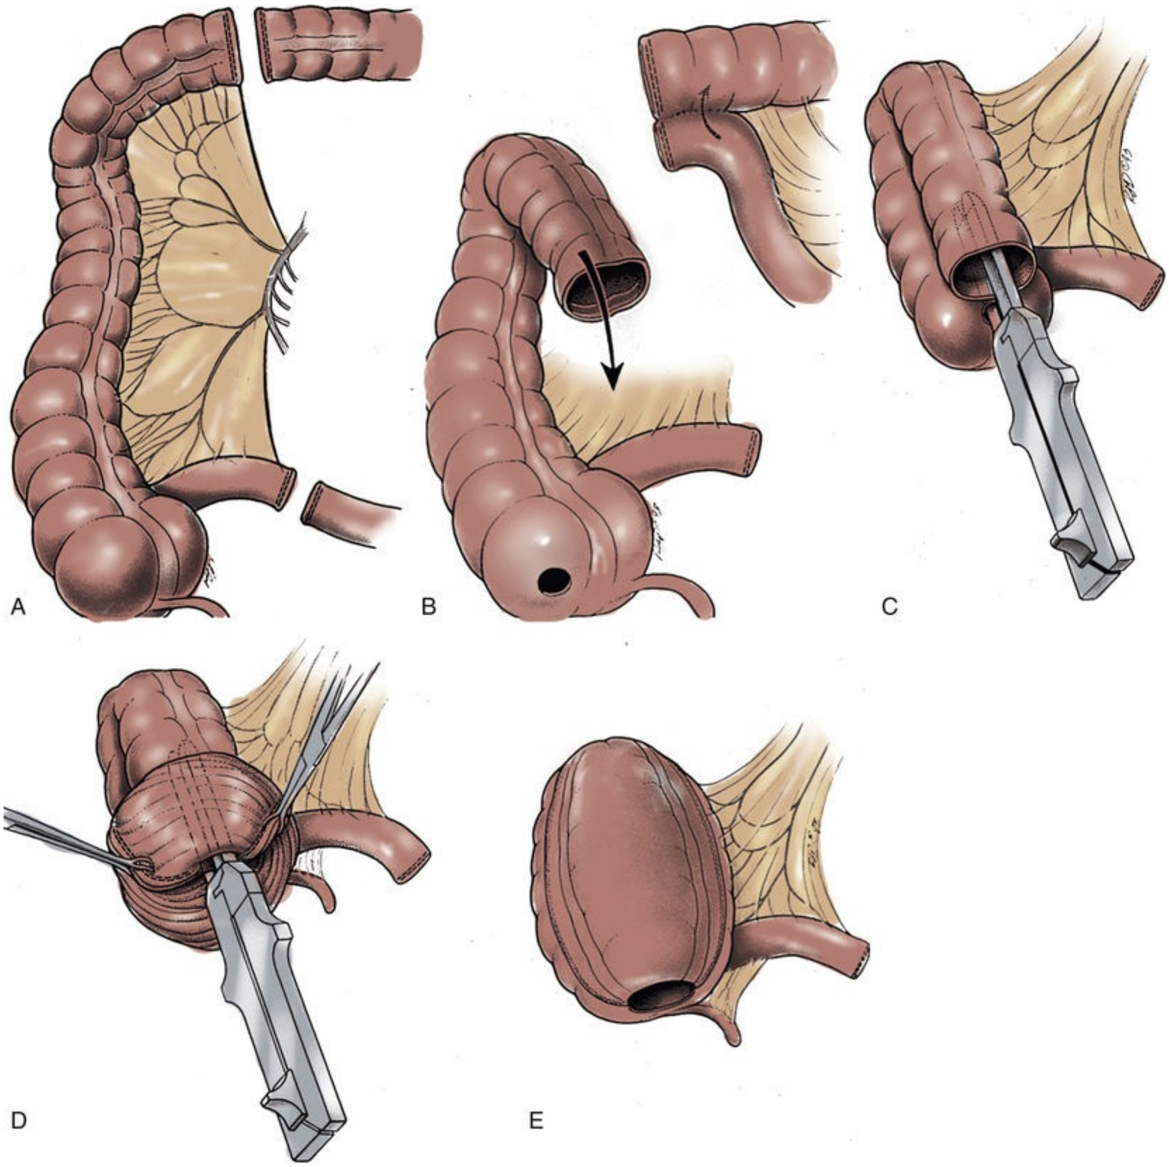

FIG. 140.17 (A) Isolation of colon and blood supply using metal gastrointestinal anastomosis staplers. (B) Opening created in cecum and open end of colon to fit absorbable stapler. Bowel continuity restored between colon and ileum. (C) Stapler activated along antimesenteric line and folded bowel. (D) Inversion of bowel required to continue staple applications. (E) Pouch inversion is complete. (From Olsson CA, Kirsch AJ, Whang MIS: Rapid construction of right colon pouch. *Curr Surg Tech Urol* 6:1–8, 1993.)

Once the generic right pouch has been fashioned, several options exist for ureteral anastomosis and formation of a sphincter mechanism. These maneuvers may be approached through the coalesced distal colon opening and cecostomy, which accesses the interior of the pouch (see Fig. 140.17E). The opening permits appropriate stent placement or inspection of a buttressed ileocecal valve. Any of the Mitrofanoff techniques described in conjunction with the Mainz I procedure can be employed. Likewise, the terminal ileum can be either stapled or plicated to create a continence mechanism. Once construction of a continence mechanism and ureteral anastomoses have been performed, the opening can be closed with a running 2-0 absorbable suture or the application of an absorbable TA stapler of appropriate length.

Continent diversion procedures commonly employ the right colon or the cecum and terminal ileum. The array of right colon pouches that can be facilitated by this technique include all of the reservoirs described previously. Reservoirs using terminal ileum and cecum such as the Penn pouch and the Mainz pouch can also be fashioned in this manner.

Stapled Sigmoid Reservoir

The same stapling maneuvers can be applied to create a reservoir constructed from the sigmoid colon (Olsson and Kirsch, 1995). A portion of the sigmoid and descending colon measuring approximately 35 cm is mobilized by incising the peritoneum along the white line of Toldt. Once mesenteric windows have been created, the segment of colon is isolated using metal GIA staplers (Fig. 140.18A). Restoration of bowel continuity is achieved with GIA, TA, or end-to-end anastomosis (EEA) staple devices.

D

FIG. 140.18 (A) Isolation of colon and blood supply using metal gastrointestinal anastomosis staplers. (B) Sigmoid bowel folded in U shape. (C) Stapler fired along antimesenteric border of folded sigmoid. (D) Oversewing of superior open end completes pouch construction. (From Olsson CA, Kirsch AJ, Whang MIS: Rapid construction of right colon pouch. *Curr Surg Tech Urol* 6:1–8, 1993.)

Each of the metal stapled ends of the isolated colon is excised, and the bowel lumen is irrigated. The isolated sigmoid is folded on itself in a U configuration, aligning both open ends (Fig. 140.18B). The absorbable GIA stapler is inserted into the open bowel ends and fired along the antimesenteric line of the folded bowel (Fig. 140.18C). Following the procedure for bowel eversion as described earlier completes the reservoir. Again, usually two or three applications of the stapler are required to complete the pouch, cutting each staple line tip to avoid staple overlap.

After bowel reinversion, ureteral implants into the taenia can be carried out, using the residual colon opening to facilitate stent passage. These stents and a suprapubic tube are led through a separate stab wound in the pouch and brought through a lower abdominal wall stab incision. A continence mechanism employing one of the Mitrofanoff variations is then performed.

W-Stapled Reservoir

Montie et al. (1994) used the absorbable GIA stapler to construct ileal neobladders in patients undergoing cystoprostatectomy. A segment of ileum measuring 50 cm is divided with a standard metal GIA stapler 20 cm from the ileocecal valve. The terminal ends of each limb of the isolated ileal segment are closed with an absorbable TA-55 stapler, and the metal staple line is resected. The bowel is aligned in a W configuration, and an enterotomy is made 10 cm from each end (Fig. 140.19A). To facilitate closure of the enterotomy with a TA instrument (Fig. 140.19, *inset*), the enterotomy must be made midway between the mesentery and antimesenteric border. The absorbable GIA device is inserted through the enterotomy and is activated. This maneuver adjoins the two adjacent bowel segments. The enterotomy may be closed with the absorbable TA-55 instrument or running absorbable suture, completing the distal segment of the W. The middle and proximal segments are constructed similarly (Fig. 140.19B). Montie stresses that the segments of the W must be offset to avoid staple lines that overlap each other. Exceeding a 3- to 6-cm overlap may result in bowel ischemia.

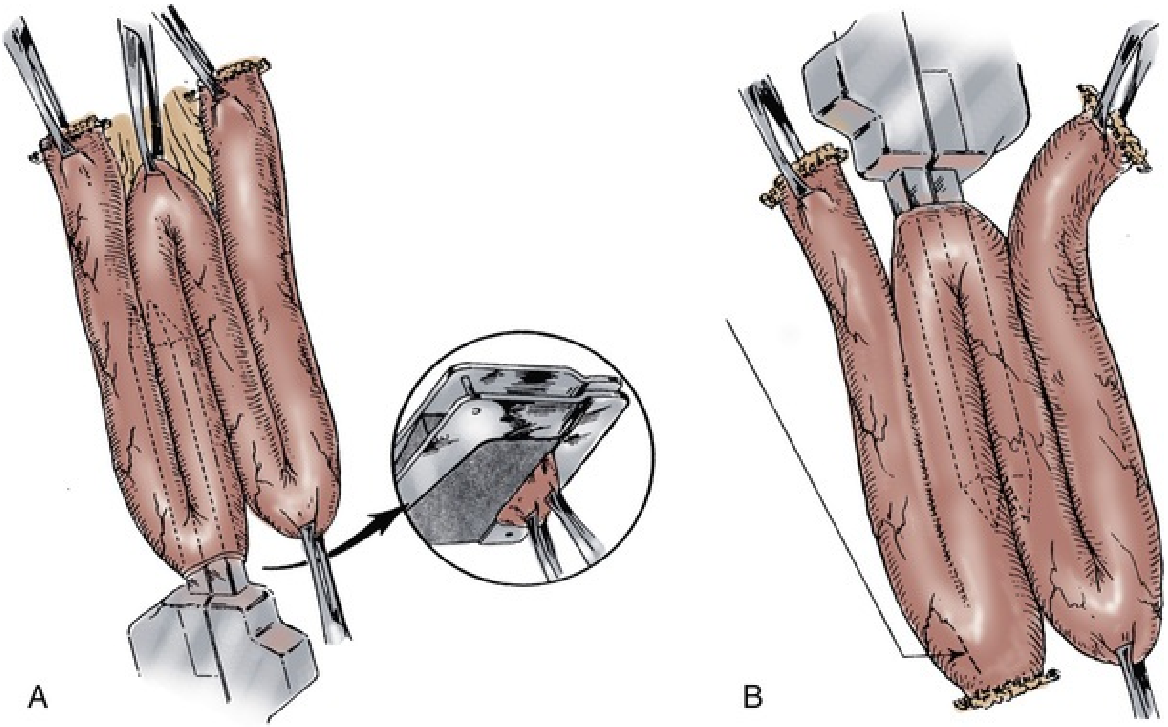

FIG. 140.19 (A) After closure of butt ends of reservoir with TA-55 stapler, enterotomy is made in dependent portion of first limb of W. Absorbable stapler is inserted through enterotomy and fired, creating common lumen between two adjacent limbs. *Arrow* indicates close-up of closure of enterotomy with TA-55 stapler. (B) In the middle limb of W, a stapler is placed through enterotomy at apex, and again, common lumen is created. Staple lines are not directly apposing for their entire distance to avoid ischemia between adjacent staple lines. *Arrow* indicates site of enterotomy where urethroileal anastomosis will be performed. (From Pontes JE: *Genitourinary oncologic pelvic surgery,* New York, 1993, John Wiley.)

Postoperative Care and Comments.

In the first 50 adult patients to undergo our absorbable stapling technique in right colon pouch construction, with at least 7 years of follow-up there have been no complications attributable to absorbable staples. Similar results have been reported by Rowland (1996). In the pediatric population, we have applied the absorbable stapler to continent urinary diversion, as well as to bladder augmentation (Hensle et al., 1995). In the first 18 children observed for up to 3 years, there have been no instances of pouch perforation or inadequate pouch capacity, and only one of the patients has developed a reservoir calculus.

Montie et al. (1994) used absorbable staplers to create W-stapled ileal neobladders in 25 patients. Ileal pouch construction was performed in approximately 20 minutes, and functional aspects were comparable with those of bowel reservoirs constructed by conventional suturing. Urodynamic evaluation at 6 months, however, documented a small-capacity reservoir requiring augmentation enterocystoplasty in 3 of 25 patients (12%). Montie et al. attributed this complication to either the size of the staples or reservoir fibrosis secondary to foreign body reaction. It is conceivable that a similar situation would arise when constructing a W-stapled T pouch.

We have used the absorbable stapler to construct large and small bowel reservoirs. In our experience, colonic pouches appear better suited for construction with the absorbable stapler because of their relatively larger lumen. **The introduction of stapling devices delivering still smaller staples and automatic staple line sealing devices may prevent the problems that occur when ileal pouches are constructed with current technology.**

Summary

In summary, continent urinary diversion is now an accepted part of the urologic surgical armamentarium. A wide array of surgical techniques exist to accomplish the desired goal of creating a continent, stoma-free, nonrefluxing pouch. There is a paucity of long-term quality-of-life studies comparing outcomes between continent cutaneous urinary diversion and ileal conduit urinary diversion. Surgeons contemplating these forms of urinary diversion should familiarize themselves with several of the techniques and the management of the most common complications.

Video 140.1 ▶ shows a bladder reconstruction procedure.

Key Points

- Because the ability to self-catheterize is essential to the patient undergoing continent diversion, the patient must be assessed for the ability to care for himself or herself.
- Patients with multiple sclerosis, quadriplegic individuals, and very frail or mentally impaired patients will at some point in their lives require the care of members of the family or a visiting nurse, and such patients are viewed as poor candidates for any form of continent diversion.
- Renal and hepatic function must be reviewed carefully in the patient selected for continent diversion. The reabsorption and recirculation of urinary constituents and other metabolites require that liver function be normal and that serum creatinine levels be in the normal range and preferably below the level of 1.8 mg/dL.
- When the ureters are directed into the fecal stream, routine colonoscopy should also be performed. There have been isolated reports of malignancy developing earlier, and all patients developing gross or microscopic hematuria should be fully evaluated.
- Many studies from throughout the world have suggested an improved psychosocial adjustment of patient undergoing continent urinary and fecal diversion compared with those patients with diversions requiring collecting appliances.

- Four general techniques have been employed to create a dependable, catheterizable continence zone. For right colon pouches, appendiceal techniques, pseudoappendiceal tubes fashioned from ileum or right colon, and ileocecal valve plication are adaptable. Appendiceal tunneling techniques are the simplest of all to perform in that they use established surgical techniques that are already in the urologic armamentarium.
- The second major type of continence mechanism used in right colon pouches is the tapered and/or imbricated terminal ileum and ileocecal valve. However, some patients have developed rather striking diarrhea and steatorrhea after the loss of the ileocecal valve. This may be particularly true in pediatric patients.
- The third surgical principle used in constructing the continence mechanism is the use of the intussuscepted nipple valve or the flap valve, which avoids the need for intussusception. The creation of nipple valves is the most technologically demanding of all the continence mechanisms and is associated with the highest complication rate.
- The fourth major technique of continence mechanism construction is the provision of a hydraulic valve, as in the Benchekroun nipple. In this procedure, a small bowel segment is isolated and a reversed intussusception is used to appose the surfaces of the small bowel.
- Pouch urinary retention represents a true emergency, and the patient must seek immediate attention so that catheterization and drainage by experienced personnel can be achieved promptly.
- Because all patients with catheterized pouches will have chronic bacteriuria, the problem of antibiotic management should be discussed. Most authors would suggest that bacteriuria in the absence of symptomatology does not warrant antibiotic treatment.
- The concept of using the buttressed ileocecal valve as a dependable continence mechanism that can withstand the trauma of intermittent catheterization was first reported from Indiana University by Rowland and Mitchell (Rowland et al., 1987).
- The Indiana pouch remains one of the most reliable of all catheterizable reservoirs. It is among the easiest to construct, and it has very low short-term and long-term complications.
- The use of absorbable staplers has substantially reduced the time required to fashion bowel reservoirs and has demonstrated short-term and long-term

reliability with respect to reservoir integrity and volume.

- Robotic technology has allowed for an increasing number of continent cutaneous urinary diversions to be achieved in a minimally invasive fashion. However, given the complex nature of these diversions, the benefits over an open approach may be limited.

Orthotopic Urinary Diversion

Eila C. Skinner MD, Siamak Daneshmand MD

History of Orthotopic Urinary Diversion

Since the early 1900s, innovative surgeons have sought the best method to replace the original bladder when it must be removed because of either benign or malignant disease. The objective of bladder substitution is to allow volitional voiding through the urethra while eliminating the need for a cutaneous urinary stoma or intermittent catheterization.

Ureterosigmoidostomy is the oldest form of urinary diversion. The first reported urinary diversion into a segment of bowel was by Simon in 1852. He attempted a ureterosigmoidostomy in an exstrophy patient by bringing the ureters into the rectum with the use of needles and suture to create a fistula. Although the patient died of sepsis 12 months later, this marked the first reported attempt at some form of urinary diversion (Simon, 1852). Ureterosigmoidostomy continued to be utilized, and the rates of obstruction and ascending pyelonephritis were significantly reduced after introduction of an antireflux tunneled anastomosis of the ureter into the sigmoid colon (Goodwin et al., 1953; Leadbetter, 1951). However, long-term hyperchloremic acidosis, ureteral obstruction and pyelonephritis, and secondary malignant neoplasms arising at the ureteral implantation site were observed (Clarke and Leadbetter, 1955; Wear and Barquin, 1973). **In 1950, Bricker refined and popularized the ileal conduit form of urinary diversion, building on an original description by Zaayer in 1911**. The ileal conduit is a technically simple, reliable form of urinary diversion that continues to be the most common form of urinary diversion performed throughout the world today for patients undergoing cystectomy.

Long-term complications with the Bricker ileal conduit started to come to light in the 1970s. **Late complications such as skin and appliance problems, peristomal hernia, stomal stenosis, pyelonephritis, kidney stones, ureteral obstruction, and renal deterioration became more apparent with longer follow-up** (Amini and Djaladat, 2017; Kouba et al., 2007; Shimko et al., 2011; Sullivan et al., 1980). These clinical sequelae were thought to be related to the high-pressure reflux of infected urine. However, nonrefluxing colon conduits had similar complications (Morales and Golimbu, 1975).

One of the earliest continent cutaneous diversions in humans was described by Gilchrist et al. in 1950 incorporating the ileocecal valve as the continence mechanism and the distal ileum as a catheterizable stoma. However, this innovation attracted little attention at the time. In 1982, Kock et al. subsequently reintroduced the concept of a continent cutaneous diversion with a technique that was originally developed for a continent ileostomy. It incorporated an intussuscepted nipple valve to maintain continence and avoid reflux. In animal experiments and then in humans, **Kock demonstrated the importance of complete detubularization of the bowel segment and the double-folding technique that creates the most spherical shape possible** (Eckman et al., 1964; Kock et al., 1982). These concepts are the cornerstone of current cutaneous and orthotopic reservoirs. After Kock described his results in his initial 12 patients, Skinner began performing this diversion in adults undergoing cystectomy for bladder cancer in 1982 and by 1987 reported on his initial series of 250 patients (Skinner et al., 1987).

The biggest challenge in the development of continent cutaneous diversion has been the design of a reliable, durable, efferent continence mechanism that is easily catheterizable. Many different techniques have been described using large and small bowel and even stomach, with many ingenious continence mechanisms. However, stones, difficulty in catheterizing, peristomal hernia, and the development of stomal leakage are potential problems with all of them, often necessitating later surgical revision (Lieskovsky et al., 1987; Rowland, 1995).

The concept of orthotopic diversion began even before Kock's continent cutaneous diversion. Tizzoni and Poggi were the first to experiment in a dog, transplanting the ureters into an isolated loop of ileum interposed between the ureters and the urethra (Tizzoni and Poggi, 1888). The dog was reportedly continent and subsequently underwent three successful pregnancies before dying 30 months postoperatively. Lemoine is credited with performing the first orthotopic reconstruction in a human subject, converting a patient from a ureterosigmoidostomy to an orthotopic diversion by transposing a segment of sigmoid to the urethral stump (Lemoine, 1913).

In 1979, Camey and Le Duc reported their pioneering clinical experience with orthotopic substitution to the native urethra in male bladder cancer patients. The initial Camey diversion used an intact segment of ileum, resulting in a high-pressure reservoir and unacceptable continence (Lilien and Camey, 1984). Subsequently, the Camey II detubularized reservoir (Camey, 1990); Hautmann W-neobladder (Hautmann et al., 1988); “hemi-Kock” neobladder (Skinner et al., 1991); Studer pouch (Studer et al., 1989); extraserosal-lined ureteral tunnel (Abol-Enein and Ghoneim, 1993); T pouch (Stein et al., 1998b);

Padua pouch (Simone et al., 2018); stomach neobladder (Hauri, 1998); cecal and ileocecal neobladders (Light and Engelmann, 1986; Månsson and Colleen, 1990); and sigmoid reservoir (Reddy and Lange, 1987) have all been described. Many of these now have a large clinical experience with long-term follow-up demonstrating good renal preservation and continence results. Orthotopic diversion quickly surpassed continent cutaneous diversion in popularity for both patients and physicians, because it allows natural voiding, is simpler to construct, and is less likely to require revision surgery at a later date.

Initially these techniques were applied only to male patients because continence in women was believed to be dependent on an intact bladder neck, and there was concern about higher local recurrence with the retained urethra. In the mid 1990s, it was discovered through anatomic dissections and initial clinical experience that women could remain continent with a low-pressure reservoir and preservation of only the urethra itself (Borirakchanyavat et al., 1997; Colleselli et al., 1998; Stein et al., 1994b) and that this was oncologically safe (Stein et al., 1998a, Stenzl et al., 1995b)

The orthotopic neobladder most closely resembles the original bladder in both location and function. This form of lower urinary tract reconstruction avoids the need for an appliance, allows volitional voiding per urethra, seldom requires intermittent catheterization, and avoids the difficulties associated with the efferent continence mechanism of continent cutaneous reservoirs.

Orthotopic diversion rapidly gained popularity during the 1990s and 2000s. Beginning in 1986, the number of orthotopic bladder substitutions performed dramatically increased to more than 75% of cystectomies at some centers, and the number of conduits and continent cutaneous diversions declined. In eight academic centers internationally polled, each with a large cystectomy experience, there was a wide range in the rate of neobladder diversion in recent years, ranging from 6% to 51% (Hautmann et al., 2013, 2015). **However, the rate of orthotopic diversion as reported in the National Bladder Cancer Database has been declining over the past decade in the United States because of unclear reasons** (Fig. 141.1). **In a population-based study in the United States using the Nationwide Inpatient Sample database from 2001 to 2008, only 8% of cystectomy patients underwent continent urinary diversion, a rate that increased only to 20%, even for patients younger than 55 years of age** (Kim et al., 2013). In one high-volume academic center, the rate of neobladder dropped dramatically from 47% to 21% over only a 5-year period from 2000 to 2005 (Lowrance et al., 2009). A more recent study using the

NSQUIP dataset showed the rate of continent diversion decreased from 23% in 2011 to 15% in 2015 (Bachour et al., 2018). In Sweden, the national rate was 14% for all patients from 2003 to 2008 (Hautmann et al., 2013).

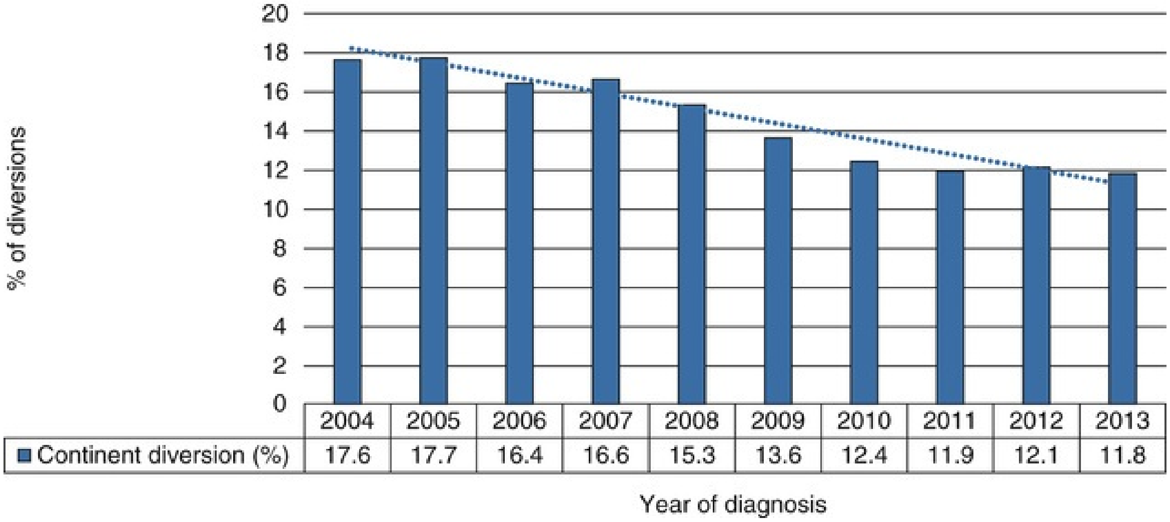

FIG. 141.1 Trend in urinary diversion in the United States from the National Cancer Database (from 27,170 patients diagnosed with primary bladder cancer undergoing radical cystectomy with urinary diversion between 2004 and 2013).

The reasons behind this generally low adoption of continent diversion and the wide variability among centers are complex. Surgeons have pointed out changes in their patient populations, such as increasing age, obesity, comorbidity, and socioeconomic challenges, and the fact that quality-of-life studies to date have not consistently shown an advantage for patients undergoing neobladder reconstruction. Chang et al. (2006) pointed out that trainees in most residency programs are exposed to few if any of these procedures. In addition, many cystectomies in the United States are performed by surgeons who do only a few such cases per year (Barbieri et al., 2007). In the United States, there is also a lack of any economic incentive for the surgeon to learn or perform a potentially more complex operation. Although many surgeons state that their patients chose ileal conduit over continent diversion, in fact, it is not difficult for the surgeon to present the options in a way that convinces the patient to choose the diversion the surgeon wants to do (Skinner, 2011). The adoption of robotic techniques may be further contributing to a move away from continent diversion, especially with a push to perform the entire diversion intracorporeally, because only a few centers have the expertise to do an entirely intracorporeal neobladder.

It is estimated that approximately 80% to 90% of male patients and 75% of female patients undergoing cystectomy are potential candidates for neobladder construction from a purely medical standpoint. In the series from Ulm, Germany, only 16% of the patients undergoing cystectomy had medical contraindications to orthotopic diversion, and another 2% refused (Hautmann et al., 2010). In another study examining the choice of urinary diversion in the context of a standardized preoperative counseling program, only 6% of patients who were eligible for a continent urinary diversion chose to undergo an ileal conduit for personal reasons (Ashley and Daneshmand, 2010). In the PROMETRICS study, the neobladder rate was 28.8% with use of neobladder associated with younger age, males, and fewer comorbidities (Schmid et al., 2015). AUA/SUO and EAU guidelines recommend that patients undergoing cystectomy should be counseled on all three options for urinary diversion (Chang et al., 2017, Witjes et al., 2016). It is incumbent on the surgeon who is counseling patients to understand the selection criteria, basic surgical techniques, and principles of perioperative management. Referral to a surgeon who performs orthotopic diversion is appropriate if the patient is eligible and interested and the treating physician is not experienced with this type of diversion.

Key Points: Historic Evolution of Orthotopic Urinary Diversion

- Urinary diversion has developed along three paths: conduit, continent cutaneous diversion, and most recently orthotopic diversion.
- Long-term complications of ileal and colon conduits include stomal stenosis, peristomal hernia, pyelonephritis, calculus formation, ureteral obstruction, and renal deterioration.
- The major long-term problems with continent cutaneous diversion relate to function of the efferent continence mechanism, and surgical revision is often required.
- The orthotopic neobladder allows for volitional voiding, avoids the need for an appliance, and only requires self-catheterization in a minority of patients.
- 80% to 90% of males and 75% of females undergoing cystectomy are potential candidates for orthotopic reconstruction.

Basic Principles of Continent Orthotopic Urinary Diversion

Three basic principles are common to all orthotopic reconstruction techniques and are key to a successful outcome. First, the patient must have an adequate external sphincter mechanism and nonobstructed urethra. Second, the reservoir must be sufficiently compliant to maintain a low pressure throughout the filling phase. This is best achieved by complete detubularization of the bowel segment and folding it to create a spherical shape. The sphere has the greatest internal volume for a given surface area. The double-folded technique of Kock and S- and W-shaped reservoirs all effectively eliminate the coordinated high-pressure contractions of the bowel wall, allowing the reservoir to maintain low internal pressure throughout the filling phase (Hinman, 1988; Kock et al., 1982).

Finally, the reservoir must have adequate volume to allow for reasonable voiding intervals. In general, this should be at least 300 to 500 mL once the pouch is mature. All bowel segments effectively stretch over time if there is adequate outflow resistance, though ileum stretches more than colon. The standard 44-cm length of ileum formed into a double-folding reservoir by the Kock technique (also used for both the Studer and T-pouch neobladders) has an initial capacity of less than 200 mL but within the first year stretches to hold 500 to 600 mL at low pressure (Studer et al., 2006). Fig. 141.2 shows a computed tomography (CT) scan of a mature spherical pouch at 1 year. A large initial volume is not necessary to ultimately achieve an adequate voiding volume.

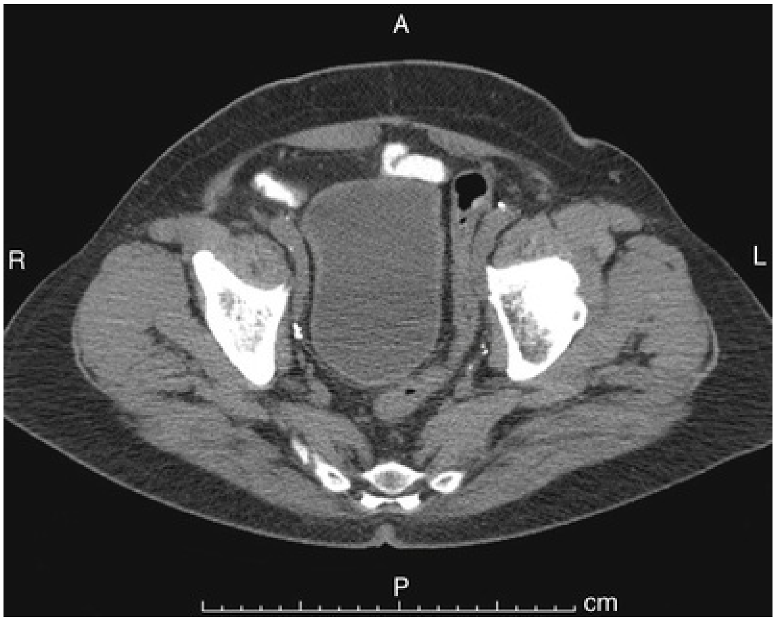

FIG. 141.2 Computed tomography scan of the pelvis after construction of an ileal neobladder (Studer pouch) showing the spheric shape achieved by 1 year.

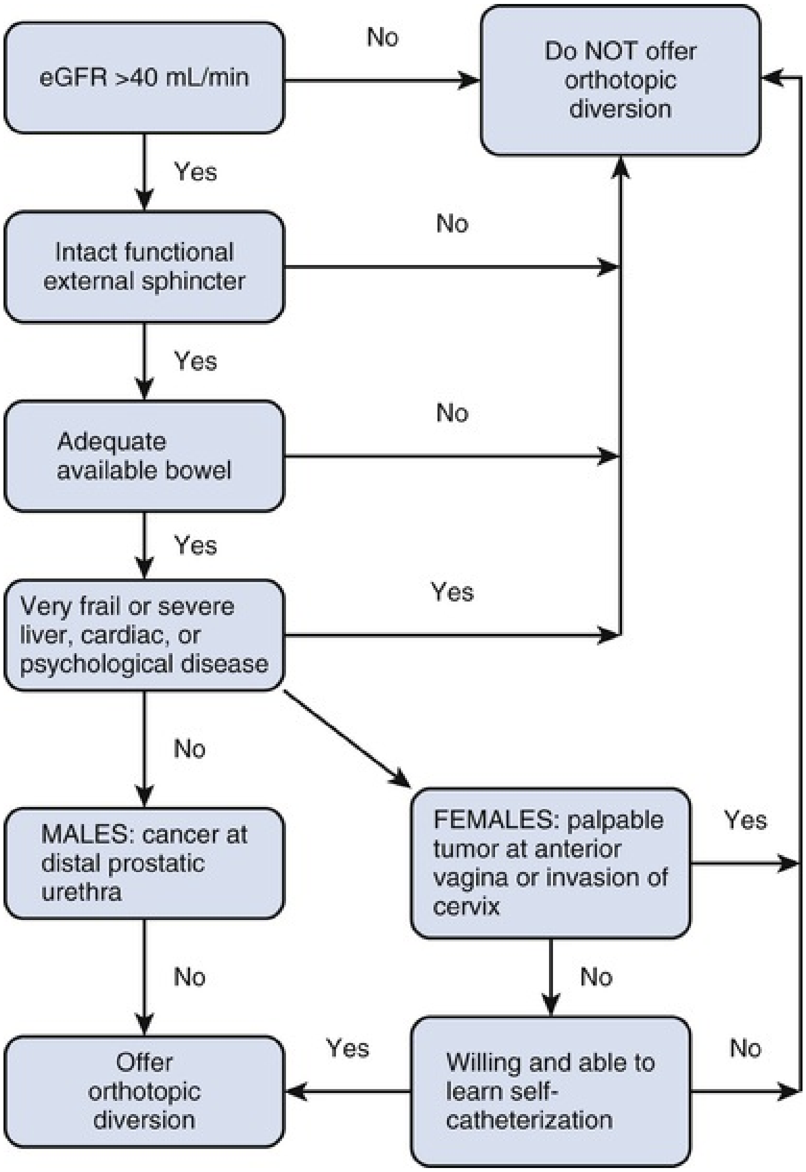
Key Points: Three Basic Principles of Orthotopic Neobladder Construction

- Patient must have a healthy urethra and adequate external sphincter function to maintain continence.
- The bowel segment used for the reservoir should be completely detubularized and reconstructed into a spherical shape.
- The ultimate storage volume of the mature pouch should be at least 300 to 500 mL at low pressure.

Patient Selection

Nearly all patients who undergo radical cystectomy may be considered at least potential candidates for orthotopic urinary diversion. There are few absolute contraindications. However, a number of factors should be considered in counseling the individual patient as to the best diversion for him or her, and these can be divided into cancer-related factors and patient factors. An algorithm for patient selection is presented in Fig. 141.3.



eGFR >40 mL/min
No
Do NOT offer orthotopic diversion
Yes
Intact functional external sphincter
No
Yes
Adequate available bowel
No
Yes
Very frail or severe liver, cardiac, or psychological disease
Yes
No
MALES: cancer at distal prostatic urethra
FEMALES: palpable tumor at anterior vagina or invasion of cervix
Yes
No
No
Offer orthotopic diversion
Yes
Willing and able to learn self-catheterization
No

FIG. 141.3 Algorithm for patient selection.

Oncologic Factors

Risk for Urethral Recurrence in Men

The primary oncologic contraindication for orthotopic diversion is the presence of urothelial carcinoma at the urethral margin on intraoperative frozen-section analysis at the time of cystectomy. In the male patient, involvement of the prostatic urethra is associated with a higher risk for subsequent urethral recurrence (Hardeman and Soloway, 1990; Moschini et al., 2017; Stein et al., 2005; Tobisu et al., 1991). In a pooled analysis of 25 series, Stenzl et al. (1995b) reported a total of 256 anterior urethral tumor recurrences in 3165 patients (8.1%) undergoing cystectomy for bladder cancer.

A retrospective review of 768 men who underwent cystectomy without urethrectomy at the University of Southern California with a 13-year median follow-up found that the overall risks for urethral recurrence were approximately 7% at 5 years and 9% at 10 years. Recurrences appeared at a median of 2 years after cystectomy (range 0.2 to 13 years). The risk was only 5% at 5 years in the 639 patients without prostate tumor involvement compared with 11% in the 129 men with prostate involvement. The extent of prostatic tumor involvement correlated with the risk for subsequent urethral recurrence. Carcinoma in situ (CIS) or mucosal and/or ductal involvement in the prostate carried a 12% 5-year estimated probability of urethral recurrence, compared with 18% for patients with invasion into the stroma. **Prostatic urethral involvement was a significant risk factor for urethral recurrence on multivariate analysis, and presence of CIS in the bladder or tumor multifocality was not** (Stein et al., 2005).

Most patients with prostatic stromal invasion also have positive nodes. Of 1550 males who underwent cystectomy from 1987 to 2008, there were 156 with prostate stromal invasion. All but 59 of these had pathologic node-positive disease, highlighting the importance of neoadjuvant therapy when prostatic stromal invasion is diagnosed preoperatively. The urethral recurrence rate for these 59 patients was 12% overall and only 6% in the 33 men who underwent orthotopic diversion. Thus urethral recurrence is relatively rare, even in those identified at higher risk who are long-term survivors (Djaladat et al., 2013).

Several other investigators have evaluated the presence of CIS in the bladder as a risk factor for urethral recurrence with variable results (Hardeman and

Soloway, 1990; Tobisu et al., 1991). Boorjian et al. (2011) reviewed more than 1500 patients (1230 males) with 13.5-year median follow-up. They found that tumor multifocality was a significant risk factor for urethral recurrence in addition to prostatic urethral involvement but not bladder CIS. Some evidence suggests that orthotopic diversion itself may provide some protection against urethral recurrence. Stein et al. (2005) reported on 397 patients who underwent neobladder diversion compared with 371 who did not. Median follow-up of both groups was long—10 years and 19 years—and patients were excluded if they underwent prophylactic urethrectomy. In patients without prostatic involvement (85% of the neobladder patients vs. 81% of the cutaneous diversion patients), the risk for urethral recurrence at 5 years was 3% versus 8%, respectively. In patients with prostatic stromal invasion, the 5-year risk for recurrence was 11% versus 24% for those with cutaneous diversion. Boorjian et al. (2011) found a similar protective effect of neobladder reconstruction in the Mayo Clinic series of over 1200 male patients with long follow-up. Both studies found that this effect persisted when other pathologic variables were controlled for. A recent meta-analysis of 14 studies including more than 6000 patients confirmed this protective effect, with a hazard ratio of 0.44 (CI 0.24 to 0.79) (Fahmy et al., 2018) for patients with orthotopic diversion. The reason for this observation is unclear, although there has been speculation that continued flow of urine, perhaps with changes in urinary characteristics caused by the interposed bowel, might contribute (Stein et al., 2005).

There is some controversy about the importance of attempting to identify prostatic urethral involvement preoperatively and what to recommend for those patients in whom prostatic involvement is identified. At the time of transurethral resection (TUR) of the primary bladder tumor, the surgeon may perform deep TUR biopsies of the prostate, preferably at the 5-o'clock and 7-o'clock positions lateral to the verumontanum. This should certainly be done if the mucosa of the prostate looks suspicious. Some authors have recommended this as a routine practice, before considering orthotopic diversion (Lerner and Shen, 2008; Sakamoto et al., 1993; Wood et al., 1989). However, others have challenged the reliability of preoperative transurethral prostatic biopsies. In a prospective series of 118 patients, Lebret et al. (1998) compared preoperative TUR biopsy of the prostatic urethra versus intraoperative frozen-section analysis at the time of cystectomy. They found that intraoperative frozen-section analysis was more accurate in predicting urethral recurrence than any preoperative parameter including preoperative prostate biopsy. In another series of 246 men, Donat et al. (2001) also found that preoperative biopsy did not accurately determine prostatic tumor involvement. Forty-three percent of patients with prostatic involvement on final pathology were missed on the TUR biopsy, and 12 of 36 patients with prostatic stromal invasion identified on TUR specimen had no residual prostatic involvement on the final cystectomy specimen. On the other hand, Von Rundstedt et al. (2016) did routine prostate urethral biopsies in 272 men and found that a negative biopsy (74% of the patients) had over 99% correlation with negative frozen section at cystectomy, perhaps obviating the need for the frozen section in that setting. The authors have not routinely recommended repeat TUR solely to rule out prostatic involvement before cystectomy. Other centers have adopted a similar philosophy with comparable clinical outcomes (Hautmann, 2003; Iselin et al., 1997).

In light of this, we have not routinely recommended repeat TUR solely to rule out prostatic involvement before cystectomy. Other centers have adopted a similar philosophy with comparable clinical outcomes (Hautmann, 2003; Iselin et al., 1997).

It has been the authors' practice to counsel patients with documented prostatic mucosal, ductal, or stromal invasion about the increased risk for urethral recurrence if the urethra is left in situ, and to help them weigh that risk against any perceived advantage of an orthotopic diversion. In general, those with prostatic stromal invasion are counseled to undergo neoadjuvant chemotherapy because of the high risk for nodal involvement at cystectomy (Djaladat et al., 2013). In those who are not candidates for neoadjuvant chemotherapy or who have persistent prostatic urethral involvement, at surgery a concomitant urethrectomy and cutaneous form of diversion are recommended. Close surveillance of the urethra is mandatory if a neobladder procedure is performed, with periodic urethral wash cytology and urethroscopy as indicated.

Risk for Urethral Recurrence in Women

In the past, urethrectomy was routinely performed at the time of radical cystectomy in women. With the acceptance of continent neobladder in men, a number of investigators began evaluating the feasibility of preservation of the urethra in women. It had been generally believed that the bladder neck was the primary continence mechanism in women, but initial clinical experience proved that one could achieve excellent continence by dividing the urethra just distal to the bladder neck (Stein et al., 1994b; Tanagho et al., 1966).

Two important pathologic studies were critical to the ultimate decision to offer urethral-preserving cystectomy and neobladder reconstruction to women with urothelial carcinoma. Stein et al. (1995) retrospectively reviewed the pathology from cystectomy specimens in 67 women who underwent cystectomy with urethrectomy for bladder cancer. Seventeen of these women (25%) had involvement of the bladder neck, and 9 of these (13% of the entire group) also had urethral involvement. All female patients with a negative bladder neck also had a negative urethra (no skip lesions), whereas approximately 50% of patients with a bladder neck tumor had concomitant urethral tumor involvement. **Risk factors for urethral involvement in this study included increased grade, stage, and lymph node involvement, but the presence of CIS did not predict urethral involvement. Vaginal wall involvement was a major risk factor for urethral involvement.** Although vaginal wall invasion was a relatively rare event (1%), all of these patients also had bladder neck involvement, and 50% had urethral extension.

Stenzl et al. (1995b) also studied the risk for synchronous or secondary urethral tumors with long-term follow-up in 356 women with bladder cancer of all stages. They found urethral involvement in only 2% of the patients, and it was always associated with bladder neck involvement. No correlation between urethral tumors and other pathologic factors such as CIS or tumor multifocality was found. **Both researchers concluded that the urethra can be safely preserved in selected female cystectomy patients provided that neither preoperative biopsy specimens of the bladder neck nor intraoperative frozen-section specimens of the proximal urethra demonstrate any tumor or severe atypia.** Several other studies confirmed that the most significant risk factor for urethral tumor involvement is tumor at the bladder neck (Chen et al., 1997; Coloby et al., 1994; De Paepe et al., 1990; Maralani et al., 1997).

Stein et al. (1998a) performed a prospective study to confirm the previously established pathologic risk factors in 72 women who had frozen-section analysis of the proximal urethra at cystectomy. Tumor involvement at the bladder neck and proximal urethra was found in 14 (19%) and 5 (7%) cystectomy specimens, respectively. **In all cases, intraoperative frozen section of the proximal urethra was correctly confirmed on final permanent section and accurately identified all patients with urethral involvement.** Stenzl et al. (1998) reported similar results.

Clinical follow-up data from the first 88 women who underwent orthotopic diversion at the University of Southern California showed that no urethral recurrences were observed with a 30-month median follow-up in this group

(Stein et al., 2002). Ali-El-Dein et al. (2004) prospectively evaluated 145 women undergoing cystectomy and orthotopic diversion. Two patients developed urethral recurrence. One had a primary squamous cell cancer of the bladder, and the other had urothelial carcinoma with CIS of the trigone. This series was updated with 180 patients and median follow-up of 57 months, with still only 2 documented urethral recurrences. There were no isolated vaginal wall recurrences. In this series, there was uterine or cervical invasion in only 1% of patients, which was suspected preoperatively in all patients based on imaging (Ali-El-Dein, 2009).

Locally Advanced Tumor Stage

Many urologists are hesitant to perform continent orthotopic diversion in patients with locally extensive disease. This is based on two factors: (1) concern about the possible impact of local recurrence on the neobladder itself and (2) a belief that these patients are doomed to suffer distant recurrence and have a shortened life expectancy and will not benefit from the neobladder.

However, Stein et al. (2001a) reported the clinical outcomes for 1054 patients who underwent radical cystectomy for bladder cancer with a median follow-up of more than 10 years. They observed an overall local pelvic recurrence rate of 7% for the entire group of patients. The risk for pelvic recurrence ranged from 6% with organ-confined, node-negative disease to 13% for patients with extravesical or node-positive disease. Nearly 50% of patients with extravesical tumor extension and 30% of patients with lymph node–positive disease were still alive without evidence of disease 5 years after cystectomy. These results suggest that local recurrence, even for patients demonstrating locally advanced or node-positive disease, is relatively infrequent and that a significant proportion of these patients will be long-term survivors and may benefit from continent diversion.

If local tumor recurrence does develop in patients with an orthotopic diversion, only a minority will have problems arise related to the urinary diversion itself. Hautmann and Simon (1999) evaluated this issue in 43 of 357 men who underwent radical cystectomy and ileal neobladder and developed local recurrence. Most of them (84%) had advanced disease (stage pT3a or higher) on final pathology at the time of cystectomy. A total of 17 patients (43%) had concomitant distant metastasis at the time of diagnosis of the local recurrence. Local recurrence interfered with the upper urinary tract in 24 patients (56%), the neobladder in 10 (23%), and the intestinal tract in 7 (16%); only 1 patient required removal of the neobladder because of an intestinal fistula. The authors concluded that **most patients could anticipate normal neobladder function, even in the presence of locally recurrent disease.** Similarly, Tefilli et al. (1999) found that 1 of 11 patients with orthotopic diversion who developed local recurrence required conversion to an ileal conduit because of invasion of the neobladder.

Based on this experience, the authors do not make decisions about appropriateness of orthotopic diversion based on presence of extravesical extension or positive nodal disease found at surgery. The exception would be a patient with grossly positive margins at the pubic bone or pelvic floor, which is a rare event.

Key Points: Oncologic Factors in Patient Selection

- The presence of CIS, multifocal tumor, or extravesical disease should not preclude orthotopic diversion if frozen section of the urethral margin is negative at surgery.
- The most significant risk factor for urethral tumor recurrence in men after orthotopic diversion is the presence of prostatic stromal invasion on final pathology.
- The most important risk factor in women for urethral tumor involvement is bladder neck or anterior vaginal wall involvement with cancer, best evaluated on bimanual examination under anesthesia.
- Intraoperative frozen-section analysis of the urethral margin accurately identifies urethral involvement in both men and women. Preoperative biopsy of the prostatic urethra or bladder neck is not mandatory.
- Local pelvic recurrence should occur in less than 10% of patients undergoing cystectomy and rarely interferes with the function of the neobladder.

Patient-Related Factors

A number of patient-related factors need to be considered when advising a patient about the best form of urinary diversion. These include the patient's general health and social circumstances, baseline renal function, presence of a healthy urethra and functioning sphincter muscle, manual dexterity, and

previous treatments including pelvic radiation, prostate surgery, or bowel resection. Perhaps equally important is the patient's personal preference and attitudes about the risk for incontinence, potential need to self-catheterize, and management of an external appliance. The relative importance of each of these factors in determining how to counsel an individual patient must be decided on a case-by-case basis. The patient and his or her family must have a realistic understanding of the pros and cons of each type of diversion before making a decision. There is a natural inclination for many patients to opt for an orthotopic reconstruction because it is the most “natural.” On the other hand, physicians may sway the discussion in favor of the simplest, quickest, and most familiar form of diversion for them to perform (Skinner, 2011). Patients must understand that problems can occur with each type of diversion, although the specific types of problems differ. An honest, informed discussion should take place, with the physician carefully explaining the various options along with the short- and long-term risks and benefits of each form of urinary diversion. It may also be helpful to have the patient talk with other patients who have undergone the various forms of urinary reconstruction. In general, patients with poor overall health, the frail elderly, and patients with high surgical risks, difficult social circumstances, or poor cognitive function are generally best managed with an ileal conduit (Daneshmand and Bartsch, 2011).

Age

Many authors have evaluated the success of continent diversion in elderly patients (Clark et al., 2005; Lance et al., 2001; Sogni et al., 2008). Although elderly patients undergoing orthotopic diversion may take longer to regain continence and have a higher rate of mild stress incontinence, ultimately older patients achieve daytime and nighttime continence rates similar to those for younger patients (Elmajian et al., 1996; Steven and Poulsen, 2000). **The clear consensus is that chronologic age alone is not a contraindication for continent diversion and that options should be considered for each patient on the basis of other factors** (Hautmann et al., 2013). Medical comorbidities; renal, cardiac, pulmonary, and cognitive function; and manual dexterity are all important factors that should be considered in the elderly, along with the patient's social support situation. A conduit may be easier for a caregiver to manage than an orthotopic diversion with the risk for incontinence and possible need for catheterization. However, an active, generally healthy, independent elderly patient may certainly be considered a reasonable candidate for orthotopic diversion depending on his or her wishes (Hugen and Daneshmand, 2016; Skinner, 2016).

Renal Function

One of the most important contraindications for continent neobladder reconstruction is compromised renal function. Urinary electrolytes including urea, potassium, and chloride are reabsorbed from the small bowel mucosa with excretion of sodium and bicarbonate, resulting in an increased acid load that must be processed by the kidneys. In patients with compromised renal function, hyperchloremic metabolic acidosis can develop along with worsening dehydration, uremia, nausea, and bone loss. The exact level of acceptable renal function for consideration for continent diversion is somewhat controversial. In one study looking at short-term change in renal function in 168 patients (124 continent diversion vs. 44 ileal conduit), the mean decrease in estimated glomerular filtration rate (eGFR) from before to after surgery in the two groups was 4.1 mL/min and 10.3 mL/min, respectively, at an 18.7-month median follow-up. There was no significant difference in this drop between those with an eGFR of 60 mL/min or higher and those with an eGFR between 40 and 59 mL/min (Winters et al., 2013). On the other hand, in a prospective study of 484 patients undergoing two types of neobladder procedures, preoperative lower eGFR was highly correlated with the risk for subsequent decline in eGFR of more than 10 mL/min by 3 years (Skinner et al., 2015). **As a general rule, a serum creatinine level of less than 1.7 to 2.2 mg/dL (150 to 200 µmol/L) or an eGFR greater than 35 to 40 mL/min/1.72 m^2 is recommended for patients considering continent diversion** (Hautmann, 2003; Hautmann et al., 2013).

However, decision making in an individual patient can at times be less clear-cut. Acute upper tract obstruction caused by the tumor often results in a transient rise in creatinine, which would be expected to improve after cystectomy and should be taken into account when counseling patients. There is no evidence that orthotopic diversion leads to worsening progressive renal dysfunction in patients with normal renal function before surgery compared with patients undergoing ileal conduit diversion (Eisenberg et al., 2014).

Body Habitus

Obesity is not a contraindication for orthotopic diversion, although placing the urethral sutures and working with the thick bowel mesentery may be challenging. **In fact, an obese patient may at times be better served with orthotopic diversion because of the difficulty constructing a functional conduit stoma with a very thick abdominal wall.**

Manual Dexterity and Willingness to Do Self-Catheterization

The need to do occasional or routine self-catheterization is reported in 10% to 20% of men and in up to 30% to 60% of women (see later). In general, it is difficult to predict which patients will require catheterization to empty, and retention can occur many years after the initial surgery. Thus **all patients considered for continent diversion should be willing and able to do self-catheterization. This is particularly important in women, in whom the potential need to do self-catheterization is higher and sometimes technically more difficult than in men.** Nearly all men are able to learn self-catheterization if necessary. Although most patients are hesitant about this potential requirement, it is rare for a patient to decide against an orthotopic diversion because of this once he or she has been educated about it.

Urethral Stricture Disease or External Sphincter Damage

Severe urethral stricture disease in men and women is a contraindication for orthotopic diversion. Poor external sphincter function in a man who is highly motivated to undergo orthotopic diversion may be managed with a concomitant or delayed artificial urinary sphincter device (Simma-Chiang et al., 2012). Similarly, a woman with significant stress incontinence might undergo a concomitant Burch or pubourethral sling procedure, although she is likely to be dependent on intermittent catheterization to drain properly if this is done.

Prior Pelvic Radiation

It is not uncommon for patients to require surgical management of invasive bladder cancer after previous failed radiation therapy or after radiation treatment of a prior pelvic malignancy. Many surgeons are hesitant to offer orthotopic diversion in this setting.

Patients with prior radiation are at increased risk for several complications, even with an ileal conduit diversion. Kim and Steinberg (2001) found an increased risk for surgical complications, especially those that required percutaneous or surgical intervention, in 23 patients undergoing cystectomy and conduit after radiation compared with 23 matched controls. Chang et al. (2004) evaluated outcomes of ileal conduits in 36 patients with prior radiation. They found that ureteroileal complications occurred in 9% of patients by 5 years and concluded that it was not necessary to use transverse colon for diversion in these patients.

The complications and ultimate functional outcome of orthotopic neobladders in patients with prior pelvic radiation have been evaluated by a number of authors. Bochner et al. (1998) described their early experience with salvage surgery and orthotopic bladder substitution after failed radical radiation therapy. A total of 18 patients who had prior radiation therapy (minimum dose, 60 Gy) for bladder or prostate cancer were evaluated. Operative characteristics, postoperative outcomes, and complications (related or unrelated to the urinary diversion) were found to be similar in irradiated and nonirradiated patients. This series was recently updated by Eisenberg et al. (2010) with a total of 48 patients undergoing neobladder reconstruction (32.4% of all patients with the same level of irradiation who underwent salvage cystectomy). Age and higher American Society of Anesthesiologists (ASA) score were associated with more early complications, but not the type of urinary diversion. However, these were clearly a highly selected group of patients who had the least visible damage to the external sphincter and were thought likely to have a good outcome. In spite of this, urinary incontinence was more common than in the larger series of nonirradiated patients.

Nieuwenhuijzen et al. (2004) reported on 27 patients who underwent salvage cystectomy, 9 of whom had an orthotopic diversion. Eight of them achieved complete daytime continence, similar to results expected in nonirradiated patients. Hautmann et al. (2009) also reported on 25 patients (18 males and 7 females) who underwent neobladder construction after high-dose irradiation. This constituted 2.5% of the entire group of neobladder patients, and one-fourth of those who underwent salvage cystectomy at that institution. Early and late outcomes were similar to those in the larger group of nonirradiated patients. Hautmann et al. concluded that indications to be considered for a neobladder in irradiated patients include absence of preoperative incontinence or stricture, no fistula formation, and no severe bowel radiation damage.

It is clear that orthotopic lower urinary tract reconstruction can be safely performed in carefully selected patients with a history of prior full-dose pelvic irradiation. Even selected women with a history of pelvic irradiation may be appropriate candidates for orthotopic reconstruction with good clinical outcomes (Lee et al., 2004; Stein et al., 2002). However, these are challenging procedures that clearly require technical expertise and keen intraoperative judgment. Previous high-dose prostate radiation (external beam or brachytherapy) or a vaginal implant for cervical cancer cause more scarring in the rhabdosphincter area than does external-beam radiation for either bladder cancer or other malignancies. Permanent brachytherapy seeds used for prostate cancer treatment often end up in the levator muscles and urogenital diaphragm and may result in severe scarring around the area of the external sphincter.

Preoperative evaluation including cystoscopy is useful to evaluate the integrity of the mucosa around the area of the sphincter. However, it may not be possible to accurately predict the degree of radiation damage found at surgery, so **careful intraoperative tissue assessment and determination of the condition of the urethra, ureters, and bowel must be performed to make a final decision about the feasibility of orthotopic diversion** (Abbas et al., 2001). These patients should always be counseled preoperatively that the orthotopic diversion may not be possible.

Prior Prostate Surgery or Bowel Resection

Prior abdominal or pelvic surgery may also present challenges for the surgeon performing orthotopic diversion. **Patients who have had a prior radical prostatectomy may have a particularly difficult dissection around the proximal urethra at the prior vesicourethral anastomosis.** Nevertheless, this is often feasible with careful dissection. The location and health of the proximal urethra can be assessed endoscopically both preoperatively and at surgery, and acceptable continence can be obtained in selected patients assuming that they had good continence before cystectomy (Huang et al., 2012; Schuster et al., 2003). Huang et al. (2012) reported on 24 patients who underwent ileal neobladder construction after cystectomy after prior radical prostatectomy (20) or prostatectomy plus adjuvant radiation (4). Nine patients had fair or poor continence before surgery, and 6 of those underwent artificial sphincter placement either at the time of cystectomy or afterward. However, 11 of the 13 men with good preoperative continence, including 1 who had both radical prostatectomy and radiation, regained good continence (0 or 1 pad per day) after neobladder construction. There were no rectal injuries and no anastomotic strictures in this series. One challenge in these surgeries is to identify the prior vesicourethral anastomosis to ensure that the bladder is entirely resected. Flexible cystoscopy at the time of the apical dissection can assist in this regard.

In conclusion, with careful dissection a patient who was continent after the initial radical prostatectomy surgery can be expected to have an acceptable result with a neobladder.

A patient with multiple prior bowel resections may be at risk for developing chronic diarrhea or even short bowel syndrome after an additional 45 to 60 cm of small bowel is resected. In these patients, alternatives to orthotopic diversion such as a sigmoid neobladder might be entertained. In general, prior bowel resections can be managed by carefully dissecting out all of the small bowel, taking down any adhesions before performing the diversion. **It is critical to identify the old bowel anastomosis and, whenever possible, take it down and use that site as one end of the continent reservoir.** This avoids potential devascularization of the bowel segment between the old and new bowel anastomoses.

Key Points: Patient-Related Factors

- Adequate renal function (eGFR >35 or 40 mL/min) is recommended for patients considering continent diversion.
- Older age and obesity are not contraindications to orthotopic diversion.
- Orthotopic diversion can be performed after prior pelvic irradiation or radical prostatectomy in carefully selected male and female patients.
- In patients with prior bowel resection, the prior anastomosis should be taken down and that segment used for the orthotopic diversion rather than choosing a new site, to avoid devascularization of the bowel.

Continence Mechanism in Patients Undergoing Orthotopic Diversion

An understanding of the anatomy of the urethral continence mechanism in men and women is crucial to preserving this function at the time of radical cystectomy. The surgical dissection at the prostatic apex in men and bladder neck in women must be carefully and precisely performed to achieve optimum continence while taking care not to compromise the oncologic effectiveness of the surgery.

In both males and females, the urethral sphincter is made up of both smooth and striated muscles. The striated rhabdosphincter appears to be the most critical for continence and is innervated by the pudendal nerve. Careful neuroanatomic dissections with three-dimensional reconstructions of male and female cadavers have defined the anatomy of the urethral sphincter mechanism (Borirakchanyavat et al., 1997; Colleselli et al., 1998; Stenzl et al., 1997; Strasser and Bartsch, 2000). In the female cadavers, Colleselli et al. (1998) found that the major portion of the striated muscle that makes up the rhabdosphincter is located on the ventral and lateral aspects of the urethra. No clearly defined line could be identified between the transverse smooth muscle cranially and the striated muscle caudally. Rather, a gradual transition was noted in the middle third of the urethra, with intermingling fibers of both types of muscle. Fluorourodynamic studies performed on women who had undergone orthotopic reconstruction after cystectomy also identified the mid-urethra as the primary continence zone (Grossfeld et al., 1996). Branches off the pudendal nerve coursing beneath the levator muscle can be traced to the rhabdosphincter. Delicate fibers from the perineal portion of the pudendal nerve course underneath the urogenital diaphragm, entering the caudal portion of the urethra laterally (Colleselli et al., 1998; Hinata et al., 2012).

In male cadavers, Strasser and Bartsch (2000) described the rhabdosphincter as an independent striated muscle that is not in direct contact with the fibers of the levator ani muscle. These dissections demonstrated that the male sphincter does not form a horizontal muscular ring around the membranous urethra. Rather, the male rhabdosphincter is also “omega-shaped” primarily ventral and lateral to the membranous urethra and prostate. The innervation of the male rhabdosphincter was also found to originate from fine branches that arise off the pudendal nerve. These authors suggested that injury to either the rhabdosphincter or the pudendal innervation may impair the sphincter mechanism in men.

Surgical Techniques for Continence Preservation During Radical Cystectomy

Anterior Apical Dissection in the Male Patient

Attention to anatomic and surgical detail is important to optimize functional and clinical outcomes in patients undergoing cystectomy with planned orthotopic diversion. Minimal manipulation of the tissue around the urethra-corresponding innervation is essential to providing optimal urinary continence (Colleselli et al., 1998; Stein et al., 2001b; Stenzl et al., 1998; Strasser and Bartsch, 2000). Most urologists are familiar with these techniques in male patients from their experience with radical prostatectomy. They may be less familiar with the dissection of the urethra and bladder neck in women.

In a standard cystectomy, the bladder and prostate are completely freed off the rectum and mobilized posteriorly before the urethral dissection. Posterior dissection should not extend distal to the apex of the prostate. If a nerve-sparing approach is planned, the urethra may be divided after the lateral pedicles are taken down to the bladder (anterior branches of the internal iliac vessels). The prostate is then dissected in a retrograde fashion off the rectum and bilateral neurovascular bundles, and the posterior pedicles are divided last.

In either approach, all fibroareolar connections along the anterior bladder wall, prostate, and undersurface of the pubic symphysis are divided. The endopelvic fascia is incised adjacent to the prostate, and the levator muscles are gently swept off the lateral and apical portions of the prostate. The superficial branch of the deep dorsal vein is identified, ligated, and divided. With tension placed posteriorly on the prostate, the puboprostatic ligaments are identified and slightly divided just beneath the pubis and lateral to the deep dorsal venous complex (DVC), which courses between these ligaments. Care should be taken to avoid any extensive dissection in this region. The puboprostatic ligaments need to be incised only enough to allow proper apical dissection of the prostate.

Several methods can be performed to properly control the DVC as discussed in Chapters 155 and 156. We use absorbable suture to avoid the risk for erosion of suture, clips, or staples into the urethral anastomosis. Once the venous complex has been ligated, it is divided close to the apex of the prostate. Any bleeding from the transected venous complex can be controlled with an absorbable suture. **Care should be taken to avoid deep suture bites into the complex or levator muscles, which could injure the continence mechanism.** The DVC suture can then be used to suspend the venous complex anteriorly to the periosteum of the symphysis pubis to reestablish anterior fixation of the DVC, which may enhance continence recovery (Bauer et al., 2011).

The anterior urethra is then incised just beyond the apex of the prostate. Six 2-0 absorbable monofilament or woven polyglycolic acid sutures are placed in the urethra circumferentially under direct vision before complete division of the urethra, carefully incorporating only the wall of the urethra without including the levator muscles. Placing the urethral sutures at this time rather than after the bladder has been removed avoids the retraction of the urethra that makes subsequent accurate placement difficult. The urethral catheter is clamped and divided distally. Two additional sutures are then placed, incorporating the rectourethralis muscle posteriorly and the caudal extent of the Denonvilliers fascia. The posterior urethra is then divided and the specimen removed. The urethral sutures are tagged to identify their location and are placed under a towel until the urethroenteric anastomosis is performed.

Frozen-section analysis of the circumferential distal urethral mucosal margin (prostatic apex) on the cystectomy specimen is performed to exclude tumor involvement. If there is tumor at the prostatic apex, the urethral stump can be excised or a total urethrectomy may be performed at this time to obtain a negative margin, and a cutaneous diversion constructed.

The contribution of prospective nerve-sparing to subsequent continence in male patients is controversial. Retrospective studies suggest continence may be improved if nerve-sparing is attempted, though in all such series it is impossible to control for the impact of selection bias (Turner et al., 1997). However, when oncologically safe it is reasonable to attempt never-sparing in a potent patient when a orthotopic diversion is planned.

Preservation of the Urethra in the Female Patient

When orthotopic diversion is considered in female patients, several technical issues should be noted to optimize the continence mechanism (Stein and Skinner, 2004; Stein et al., 2001b). A standard female cystectomy includes removal of the uterus, cervix, and ovaries (anterior exenteration). However, in selected female patients with clinically lower-stage disease, a number of authors have advocated preservation of the uterus and ovaries (Ali-El-Dein et al., 2013; Chang et al., 2002; Djaladat et al., 2012; Zippe et al., 2005). It appears that preserving the uterus and its supportive ligaments eliminates the risk for vaginal fistula, improves sexual function, and may decrease late urinary retention in women undergoing neobladder reconstruction (see later). If the uterus is preserved, the branches of the internal iliac artery feeding the bladder are taken distal to the takeoff of the uterine artery, and the ureteral stump must be dissected from below the uterine artery. Whether the uterus is removed or not, **whenever possible the bladder is dissected completely off the anterior vaginal wall rather than excising it. However, a deeply invasive tumor on the posterior bladder or trigone may necessitate excision of a portion of the anterior vaginal wall.** This does increase the risk for subsequent pouch-vagina fistula but is not an absolute contraindication to orthotopic reconstruction. **A patient with a significant tumor at the bladder neck or with palpable extension into the vaginal wall is a poor candidate for neobladder and should undergo en bloc urethrectomy and cutaneous diversion.**

In developing the posterior pedicles, if a hysterectomy is planned the posterior vagina is incised at the fornix behind the cervix. If the patient has undergone prior hysterectomy, a sponge stick in the vagina facilitates identification of the vaginal apex. In this case, the vagina is usually not entered. Before dissecting off the bladder, the posterior vascular pedicles coursing around the vagina to the bladder are developed and divided with hemoclips, vascular staples, or a LigaSure (Covidien, Mansfield, MA) or similar device.

There is controversy about the importance of preserving the nerves along the lateral vagina in women. Some authors have suggested that preservation of this tissue may contribute to maintaining continence and avoiding retention in women undergoing orthotopic diversion (Bhatta et al., 2007, Gross et al., 2015; Hautmann, 1997; Stenzl et al., 1995a, 1998; Turner et al., 1997). Others have not made any special effort to preserve the autonomic nerves and have successfully relied on the pudendal innervation of the rhabdosphincter complex for continence (Ali-El-Dein, 2009; Ali-El-Dein et al., 2002; Stein et al., 1997, 2004). This is a difficult question to test, and there are no randomized trials testing this question (Skinner and Comiter, 2015). However, although not absolutely required, it is reasonable to preserve these nerve bundles if possible in women undergoing neobladder reconstruction.

Once the posterior pedicles have been divided, careful dissection of the bladder off of the anterior vaginal wall is performed sharply. Care must be taken to dissect in the proper plane to prevent entry into the posterior bladder and reduce the amount of bleeding in this vessel-rich area. **It is absolutely critical not to compromise the oncologic success of the surgery by inadvertent incision into the bladder.** Dissection is carried caudally to the vesicourethral junction. Tugging on the Foley catheter balloon to position it at the bladder neck assists in identifying this junction.

Once the posterior dissection is completed, the fatty tissue overlying the anterior urethra is swept off the endopelvic fascia and the vesicourethral junction is carefully identified. Again, tugging on the Foley catheter, if necessary with extra water in the balloon, allows the surgeon to visualize the junction between the urethra and bladder. **The endopelvic fascia and periurethral tissue anteriorly should not be disturbed in this process. The proximal urethra in the female extends well above the endopelvic fascia** (Fig. 141.4). Careful sharp dissection is used to free the bladder neck and an initial 0.5 cm of urethra off the vagina. At this point, the specimen is attached only by the urethra itself.

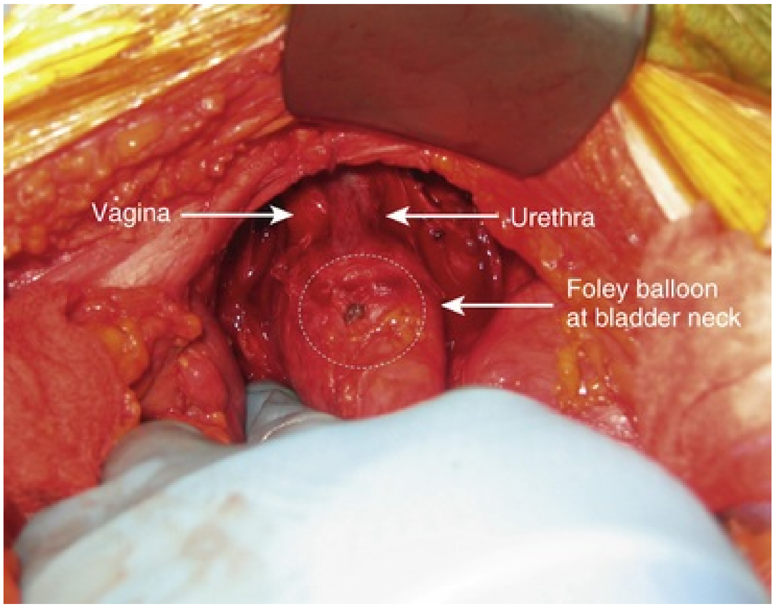


FIG. 141.4 Intraoperative photo of preparation of the female urethra for an orthotopic neobladder. The fatty tissue overlying the anterior urethra is swept off the endopelvic fascia, and the vesicourethral junction is carefully identified by positioning the Foley catheter at the bladder neck (20 cc of water in the catheter balloon can facilitate this). Note that the endopelvic fascia and periurethral tissue anteriorly are not disturbed.

After the site for the incision is marked just distal to the vesicourethral junction, the Foley catheter can be removed and a pedicle clamp placed across the bladder neck, which prevents any tumor spill from the bladder when the urethra is transected. The proximal urethra is sharply divided just distal to the bladder neck. The female urethra does not retract away after division as it does in the male, so sutures can be placed after removal of the bladder. Frozen-section analysis is performed on the urethral margin of the cystectomy specimen to exclude any tumor. Once the decision is made to perform the orthotopic diversion, 8 to 10 individual 2-0 absorbable sutures are placed circumferentially through the urethra, tagged, and set aside.

In the case of a deeply invasive posterior bladder tumor, the anterior vaginal wall may be removed en bloc with the cystectomy specimen by incision along the long axis of the anterolateral vaginal wall. This leaves the anterior vaginal wall attached to the bladder specimen. Again, the Foley catheter balloon facilitates identification of the vesicourethral junction. A rim of anterior vaginal wall must be preserved proximal to the urethra to close the vagina so that the vaginal suture line is not directly abutting the vesicourethral suture line to decrease the risk for subsequent fistula. The vagina may be closed in a clamshell or horizontal manner. Other reconstructions to increase vaginal volume are feasible, but it may be difficult to perform a complex vaginal reconstruction (e.g., a rectus myocutaneous graft) along with a neobladder procedure simply because of a lack of adequate room in the pelvis.

The vagina is then closed at the apex with absorbable suture and then suspended. One may suspend the vagina to the Cooper ligament or to preserved cut ends of the round ligaments to prevent postoperative vaginal prolapse. However, we routinely perform a sacrocolpopexy incorporating a short strip of permanent mesh to fix the vagina to the sacral promontory at a more natural angle without any tension. This may be important to support the neobladder and avoid a possible cause of late voiding difficulty. **Regardless of the form of vaginal reconstruction, a well-vascularized omental pedicle graft should be placed between the reconstructed vagina and the neobladder and secured to the endopelvic fascia at either side of the urethral stump to separate the suture lines and prevent fistula formation between the vaginal and urethral anastomosis, and to help support the pouch posteriorly.** Videos 141.1 and 141.2 show the dissection of the bladder neck and proximal urethra in the female cystectomy.

Key Points: Continence Mechanism and Surgical

Techniques for Continence Preservation

- The striated rhabdosphincter muscle fibers and associated innervation from the pudendal nerve are concentrated in the area anterior and lateral to the proximal urethra in both males and females.
- In male patients, one should obtain careful control of the DVC, and avoidance of deep suture bites into the pelvic floor muscles is critical.
- In female patients, the endopelvic fascia and levator muscles should not be disturbed.

Techniques for Orthotopic Bladder Substitution

Choice of Bowel Segment

A number of different procedures for orthotopic reconstruction incorporating different segments of bowel have been described. There are clearly some physiologic indications to use various segments of intestine, but the surgeon's preference may be even more influential. It has been suggested that **excellent functional and clinical outcomes with voiding can be achieved regardless of the segment of bowel chosen as long as the principles of preservation of the rhabdosphincter as a continence mechanism and construction of an adequate capacity, low-pressure reservoir are maintained** (Lee et al., 2003; Parekh et al., 2000b). Ideally, the surgeon performing orthotopic urinary diversion will be comfortable using a variety of the techniques described later so that he or she can adapt the technique to the needs of the individual patient.

Reservoirs made of detubularized ileum or ileum and colon together appear to have the greatest compliance and lowest likelihood of generating intermittent high-pressure contractions. Hohenfellner et al. (1993) elegantly evaluated the properties of gut smooth muscle layers (circular and longitudinal) of ileal and cecal segments in a canine model. The circular muscle layer of ileum was found to be most distensible, followed by the colonic circular and longitudinal ileal layers. The longitudinal layer of the colonic segment was relatively nondistensible. Studies in humans showed that the urodynamic characteristics of the ileum appear to be superior to those of the colon (Berglund et al., 1987; Chen et al., 2009; Davidsson et al., 1992; Schrier et al., 2005). Stomach and sigmoid colon have been found to have particularly poor compliance and high pressures (Santucci et al., 1999). Schrier et al. (2005) found that neobladders made of ileum had a larger capacity, lower filling pressures, lower maximum capacity pressures, and better compliance. The distal small bowel mesentery also tends to have the greatest mobility and almost always reaches the urethra without much difficulty. In patients with short ureteral length because of malignancy or other pathology of the ureters, an ileal pouch with an afferent limb (such as the Studer) can be extended to reach all the way to the renal pelvis. A final advantage of ileum is the atrophy of the intestinal mucosa as it is exposed to urine over time. This results in decreased mucous production and decreased reabsorption of urinary electrolytes in the mature reservoir. Mucosal atrophy appears to be more reliable in small bowel than in large bowel reservoirs (Mills and Studer, 1999; Norlen and Trasti, 1978). Interestingly, the intestinal epithelial cells also lose their tissue-specific epigenetic profile with time when exposed to urine. De novo methylation of some intestine-specific enhancers occurs with concomitant demethylation of primarily non–intestine-specific transcribed regions (Lay et al. 2014).

The primary disadvantage of using distal ileum lies in the potential loss of absorption of vitamin B_{12}. This segment may also have been unacceptably damaged by prior pelvic radiation or may be unavailable because of multiple prior bowel resections or inflammatory conditions such as Crohn disease. Whenever ileum is available, we preferentially use it for orthotopic diversion.

Bladder replacement using stomach has also been described, although it has not been a popular technique (Hauri, 1998; Lin et al., 2000). The purported advantage of gastric segments is that the gastric mucosa excretes chloride and hydrogen ions, effectively reversing the acidosis of renal insufficiency. The excreted acid from a stomach segment can also reduce the risk for bacterial colonization, and there is less mucous production. However, the disadvantage of using stomach is that compliance is poorer than ileum, and some patients will develop dysuria or hematuria from the excreted acid (Lin et al., 2000). Combining gastric and small or large intestinal segments can counteract some of these side effects and may be ideal from a purely metabolic standpoint (Lockhart et al., 1993). This construction can theoretically be performed in a patient with compromised renal function when continent diversion is contraindicated. It may also provide another option in a patient with prior high-dose pelvic radiation or multiple previous bowel resections. Few urologists have been trained in the surgical anatomy of the stomach, and most who perform a significant number of cystectomies currently rarely, if ever, use this type of diversion.

Isolation of the segment of bowel to be used for the diversion must be performed carefully to preserve blood supply to the pouch and to the bowel anastomosis. If using ileum, one should avoid deep incision into the mesentery at the proximal bowel division to avoid compromising the blood supply to the reservoir. In addition, in patients who have had previous bowel resection, it is important to take down the old anastomosis rather than choosing another site nearby because that could result in a poorly vascularized segment between the new and old bowel anastomoses.

Need to Prevent Reflux

The deleterious effect of vesicoureteral reflux in children is well accepted, especially in the face of infection. In the context of urinary diversion, the importance of reflux was first identified in patients undergoing ureterosigmoidostomy (Clarke and Leadbetter, 1955) and, subsequently, ileal conduit urinary diversion (Middleton and Hendren, 1976). It was previously believed that high-pressure reflux of infected urine may be the cause of upper tract deterioration (Clark et al., 1999; Madersbacher et al., 2002). Age, hypertension, ureteroenteric anastomotic stricture, and pyelonephritis have been reported as independent risk factors for renal function deterioration in different series. Type of urinary diversion, however, does not seem to be a predisposing factor for renal dysfunction (Amini and Djaladat, 2017).

Studies that have compared refluxing versus nonrefluxing urinary diversion have been limited, in general, by short follow-up, patient selection bias, retrospective design, or relatively small patient numbers. Richie et al. (1974) initially showed a protective effect of nonrefluxing anastomoses in a dog model. Kristjánsson et al. (1995a,b) later found no difference in colon conduits with nonrefluxing anastomoses versus ileal conduits with refluxing anastomoses. However, continent diversions with antireflux techniques appeared to result in less upper tract scarring and bacteriuria. Song et al. (2006) and Hautmann et al. (2006) each found no differences in renal function or hydronephrosis in refluxing or nonrefluxing orthotopic neobladders in nonrandomized retrospective studies. These studies were retrospective and nonrandomized and in general included relatively small numbers of patients.

With orthotopic diversion, most patients void by Valsalva maneuver with relaxation of the external sphincter. The resulting increase in pressure in the reservoir should be transmitted equally to the rest of the system, limiting any resulting back pressure even without an antireflux mechanism (Studer et al., 2006; Thoeny et al., 2002). However, free reflux into the upper tracts of the Studer pouch is often visible on cystogram with as little as 300 mL of filling, well within the typical voided volume of these patients. It is likely that there is some low-pressure retrograde flow of urine in these patients at times. In patients who require intermittent catheterization to empty, such reflux could potentially occur at relatively high pressures when the reservoir is full. Finally, although symptomatic infections are uncommon (see later), it is not unusual for these patients to have asymptomatic bacteriuria, especially if they are performing self-catheterization. Steven and Poulsen (2000) reported 34% 3-year and 24% 5-year prevalence rates for bacteriuria in 166 men undergoing orthotopic reconstruction.

Medium- to long-term results with a refluxing type of reservoir such as the Studer pouch suggest that normal renal function and preserved upper tract anatomy are possible in the majority of patients (Minervini et al., 2005; Perimenis et al., 2004; Studer et al., 2006; Thoeny et al., 2002). Thoeny et al. (2002) examined long-term results in 76 patients with a Studer pouch with 5 or more years of follow-up and found preserved renal function and anatomy in 95% of the patients.

It is clear that any mechanism introduced to prevent reflux may also potentially cause upper tract obstruction. Initial experience with the intussuscepted Kock nipple valve showed that it provided reliable protection against reflux and seemed to have few drawbacks. However, as surviving patients were followed up to 10 years and beyond, it became clear that a significant proportion of patients experienced obstruction from stenosis of the afferent nipple valve or extussusception of the afferent nipple valve (Stein et al., 1996). In addition, at least 25% form stones over time (Arai et al., 1993; Ginsberg et al., 1991). Afferent valve obstruction is often clinically silent. Patients who were not followed carefully occasionally developed acute renal failure and bilateral hydroureteronephrosis with significant renal damage, underscoring the need for careful lifetime follow-up in patients with urinary diversion. Similarly, ureteroileal obstruction with the antireflux Camey-Le Duc ureteral implantation technique has been reported to occur in 7% to 29%, compared with less than 3% for a direct ureteroileal anastomosis (Le Duc et al., 1987; Pantuck et al., 2000; Roth et al., 1997; Shaaban et al., 1992).

Abol-Enein and Ghoneim developed a serous-lined ureteral implantation technique with an ileal neobladder and reported their intermediate experiencein 2001 in 450 patients with median follow-up of 38 months. In this large series, 96% of upper tracts remained unchanged or improved; reflux was observed in only 3% of patients. Anastomotic ureteral stricture occurred in 3.8% of patients, an incidence similar to that of most refluxing ureteroileal anastomoses (Abol-Enein et al., 2001; Pantuck et al., 2000; Shah et al., 2015). The T pouch was designed building on this technique to provide protection from reflux while avoiding some of these complications of the Kock nipple valve. This is accomplished by preserving optimum blood supply to the tunneled ileal afferent limb segment while allowing the ureters to be directly implanted into the ileum, allowing for ureters that are dilated or must be divided high (Stein and Skinner, 2006; Stein et al., 1998b). With a 33-month median follow-up, renal function and anatomy were preserved in 90% of patients, with only 2% developing stenosis related to the afferent T limb during this time (Stein et al., 2004). In recent years, the technique has been modified to avoid tapering the afferent limb in an attempt to further limit the development of late stenosis, a complication that increases in frequency with further follow-up.

Shaaban et al. (2006) performed a small prospective randomized clinical trial evaluating whether prevention of reflux is beneficial. They studied 60 patients who all had normal renal function preoperatively and no hydronephrosis. In each patient, one randomly chosen ureter was implanted in an antireflux manner (using an extraserosal tunnel), and the other was implanted directly into a small tubularized chimney on a standard W ileal neobladder. At a 2-year median follow-up, the researchers found more deterioration in the renal units drained with the antireflux technique, which resulted in five cases of documented obstruction, than in those with a direct refluxing anastomosis.

The authors recently completed a larger prospective randomized trial with 484 patients undergoing radical cystectomy randomized to receive either a Studer or T pouch urinary diversion. At 3 years, there were no differences in renal function or urinary tract infections between the two groups. However, the patients with the T pouch were more likely to require diversion-related secondary procedures than those with the Studer construction (Skinner et al., 2015).

As treatment for bladder cancer improves and patients live longer after cystectomy and urinary diversion, they are at further long-term risk for renal deterioration, and reflux prevention may become a more important issue. The question remains whether any benefit in upper tract protection afforded by the antireflux technique outweighs the potential risk for upper tract obstruction from the antireflux technique itself. Further clarification of this question awaits the long-term results of these prospective randomized trials.

Key Points: Choice of Bowel Segment and the Need to Prevent Reflux

- Reservoirs made from ileum or combined ileum and colon appear to have the best physiologic properties for orthotopic diversion.
- Isolation of the segment of bowel to be used for the diversion must be

performed carefully to preserve blood supply to the pouch and bowel anastomosis.

- The addition of an antireflux mechanism does not appear to be necessary for preservation of the upper tracts and prevention of infection, at least in the intermediate term.

General Perioperative Management

Perioperative management of patients undergoing cystectomy and orthotopic diversion is not significantly different than for patients undergoing other types of diversion. Preoperative history should focus on prior abdominal or pelvic surgery or radiation, current voiding patterns and continence, general medical problems and social support, and patient priorities and preferences. If colon may be used for the diversion, a colonoscopy is recommended to rule out polyps or tumors. Preoperative risk stratification using a frailty index and cardiopulmonary exercise testing for high-risk patients should be performed. There is evolving evidence that preoperative optimization of the patient through nutritional and preoperative exercise intervention may improve surgical outcomes (Cui et al., 2017).

There is no consensus on the ideal management of ureteral stents or catheters in patients undergoing orthotopic diversion. Most authors recommend the use of ureteral stents in the early postoperative period (Mattei et al., 2008). We use 8-Fr pediatric feeding tubes or 7-Fr single-J urinary diversion stents and tie them to the urethral catheter so they can be removed at the same time and the patient has fewer external bags to manage. We also use a 24-Fr stiff hematuria catheter, which facilitates routine irrigation of the pouch and is left in for approximately 3 weeks. Other surgeons alternatively use externalized ureteral stents brought through the skin in addition to a separate suprapubic tube, which are drained separately. The latter allow for less urine to pass through the pouch while it is healing and may decrease dependence on attentive nursing. However, this may be cumbersome for patients and could potentially limit their mobility during the immediate postoperative period. A pelvic drain should be placed in every patient. In general, we leave the drain until the pouch has healed because of occasional late leakage if the catheter gets plugged at home.

Postoperative hospitalization in the past averaged approximately 8 to 10 days, primarily because of delayed feeding and postoperative ileus. We have adopted an Early Recovery after Surgery (ERAS) protocol that has allowed routine discharge 3 to 5 days after surgery (Daneshmand et al., 2014). The protocol includes avoiding bowel preparation and nasogastric tubes, decreasing narcotic pain management (including epidural narcotics), instituting early feeding, and using a μ-opioid antagonist that blocks the effects of narcotics on the bowel. Use of the μ-opioid antagonist alvimopan has been associated with a reduction in hospital stay in numerous randomized trials in colorectal surgery and a Phase IV double-blind, placebo-controlled randomized trial of 280 cystectomy patients (Lee et al., 2014; Sultan et al., 2017). Other components vary among programs, and the individual contribution of each component to the overall pathway is less well studied (Karl et al., 2014). Enhanced recovery protocols have now been adopted for radical cystectomy patients in many institutions. No significant differences in overall, minor, or major complications have been observed between the ERAS and control groups. Multiple series have demonstrated the capacity for ERAS protocols to improve outcomes among patients undergoing radical cystectomy through decreased incidence of gastrointestinal complications and decreased length of hospitalization without increased readmissions or overall morbidity (Bazargani et al., 2018; Djaladat et al., 2017; Ramirez et al., 2013). A recent meta-analysis of 13 distinct ERAS studies revealed a lower overall complication rate (especially minor Clavien grades) and faster return of bowel function in the ERAS group (Tyson and Chang, 2016).

Patients are usually seen around postoperative day 10 for follow-up and laboratory evaluation, and drain removal if there is minimal drainage (<100 mL per 24 hours). When patients return 3-weeks postoperatively, the catheter is removed. Routine pouchograms or radiographic studies of the neobladder are not routinely performed unless a significant output from the drain is observed. Patients receive education throughout the perioperative period regarding catheter management, pelvic floor exercises, and proper voiding technique at time of catheter removal.

Surgical Techniques

A large number of modifications of the techniques presented next have been described in a small number of patients, and this is by no means an exhaustive list.

Ileal Reservoirs

Most ileal reservoirs use from 60 to 75 cm of terminal ileum, which is detubularized and folded in a variety of ways to attempt to create a spheric shape. Modifications primarily include variations in the exact folding technique and variations in management of the ureters, with or without an antireflux mechanism. In general, all reservoirs are closed with continuous absorbable sutures. **The use of nonabsorbable suture and metal staples should be avoided because of the potential for stone formation** (Stein et al., 1994b; Suriano et al., 2013). Absorbable staples have been developed, although they tend to be somewhat difficult to use with inconsistent results and thus are not in routine use today (Montie et al., 1996; Olsson et al., 1995).

The two most popular configurations around the world are the Hautmann W-neobladder (and its various modifications) and the Studer pouch neobladder. Both are relatively simple constructions and allow direct ureteroileal anastomosis, which has been shown to have the lowest risk for subsequent stricture. The T pouch and extraserosal tunnel techniques both provide an antireflux mechanism when that is felt to be advantageous (Hugen and Daneshmand, 2016).

Camey II

The Camey II orthotopic substitute (Camey, 1990) is a modification of the original Camey bladder substitute (Lilien and Camey, 1984), which was a simple segment of ileum anastomosed to the ureters and urethra (Fig. 141.5). The modification includes detubularization and folding to eliminate peristaltic activity. A total of 65 cm of ileum is isolated, with an area of the ileum identified to reach to the region of the urethra in a tension-free manner. After the integrity of the bowel is restored, the mesenteric trap is closed and the isolated portion of ileum is opened along the antimesenteric border for the entire length, except the area previously identified for the urethral anastomosis. In this region, the ileal incision is directed toward the mesenteric border. The ileum is then placed in a transverse U orientation. The medial borders of the U are sutured together with a running absorbable suture. A fingertip opening is made in the preselected area for the ileourethral anastomosis, the entire ileal plate is brought down to the pelvis, and the urethral anastomosis is performed. The ureteroileal anastomosis is then performed via the Le Duc technique (Le Duc et al., 1987). The reservoir is completed by folding the ileal plate and suturing with a running absorbable suture. The ends of the U are anchored to the pelvic floor to reduce tension (see Fig. 141.5). A modification of the Camey II has been described by Barre et al. This forms the ileum in a Z configuration and reportedly has the advantages of shorter length requirements, improved reservoir capacity, and potentially improved functional (continence) results (Barre et al., 1996). A modification using gastrointestinal anastomosis (GIA) metal staples for rapid construction has also been described (Muto et al., 2016).

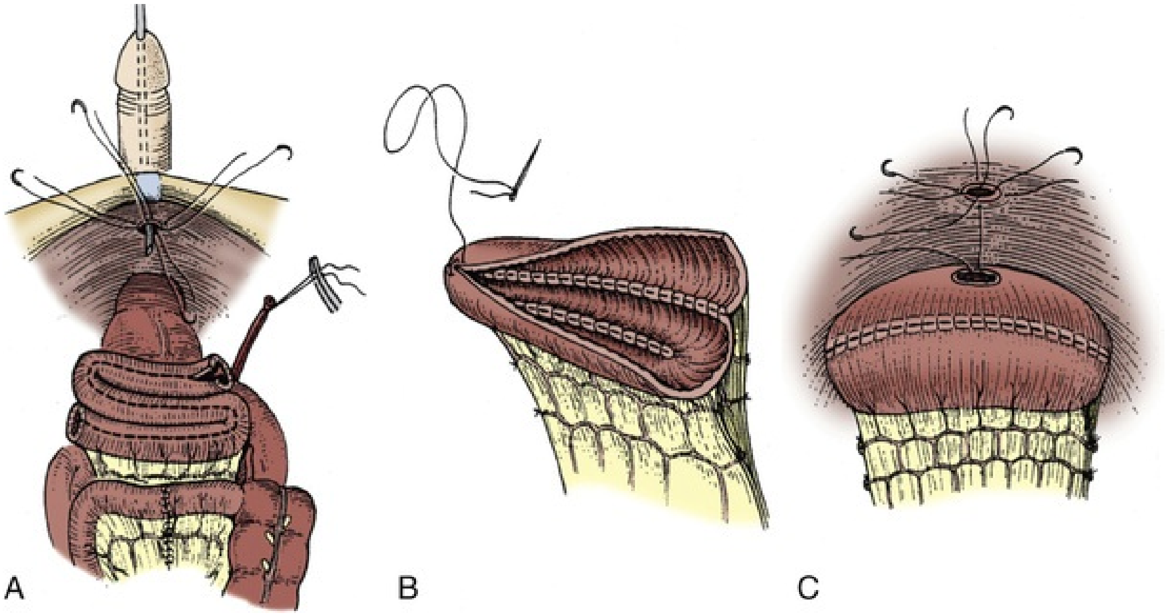

FIG. 141.5 Construction of the modified Camey II neobladder. (A) The ileal loop is folded three times (*Z* shaped) and incised on the antimesenteric border. (B) The reservoir is closed with a running suture to approximate the incised ileum. (C) The urethral anastomosis is performed, and the ureters are implanted using the Le Duc antireflux technique.

Orthotopic Kock Ileal Reservoir (Hemi-Kock)

The Kock ileal reservoir was first used as a continent cutaneous ileal reservoir incorporating intussuscepted nipple valves for both the afferent (antireflux) and efferent (continence) limbs (Kock et al., 1982; Skinner et al., 1984) (Fig. 141.6). This subsequently evolved into an orthotopic form of diversion in which the afferent intussuscepted limb was maintained to prevent urinary reflux (see Fig. 141.6) (Ghoneim et al., 1987; Skinner et al., 1991). Skinner et al. performed more than 500 of these procedures from 1982 to 1995, with excellent continence and a low ureteroileal stricture rate of less than 3% (Skinner et al., 1988; Elmajian et al., 1996). Schreiter and Noll (1989) described an S-shaped modification of the orthotopic Kock ileal reservoir. With long-term follow-up, late complications associated with the afferent intussuscepted antireflux nipple developed in a small but significant number of patients (Stein et al., 1994a, 1996). These included stone formation on exposed staples, stenosis of the afferent nipple ostium thought to be secondary to a compromised blood supply, and extussusception or prolapse of the afferent limb. These complications often occurred more than 10 years after construction of the reservoir and were clinically silent until the patient developed bilateral hydronephrosis or even renal failure (Stein et al., 1996). The technical difficulty of the intussuscepted nipple valve and the associated complications, along with the development of effective alternative techniques, has made this neobladder procedure less commonly used today.

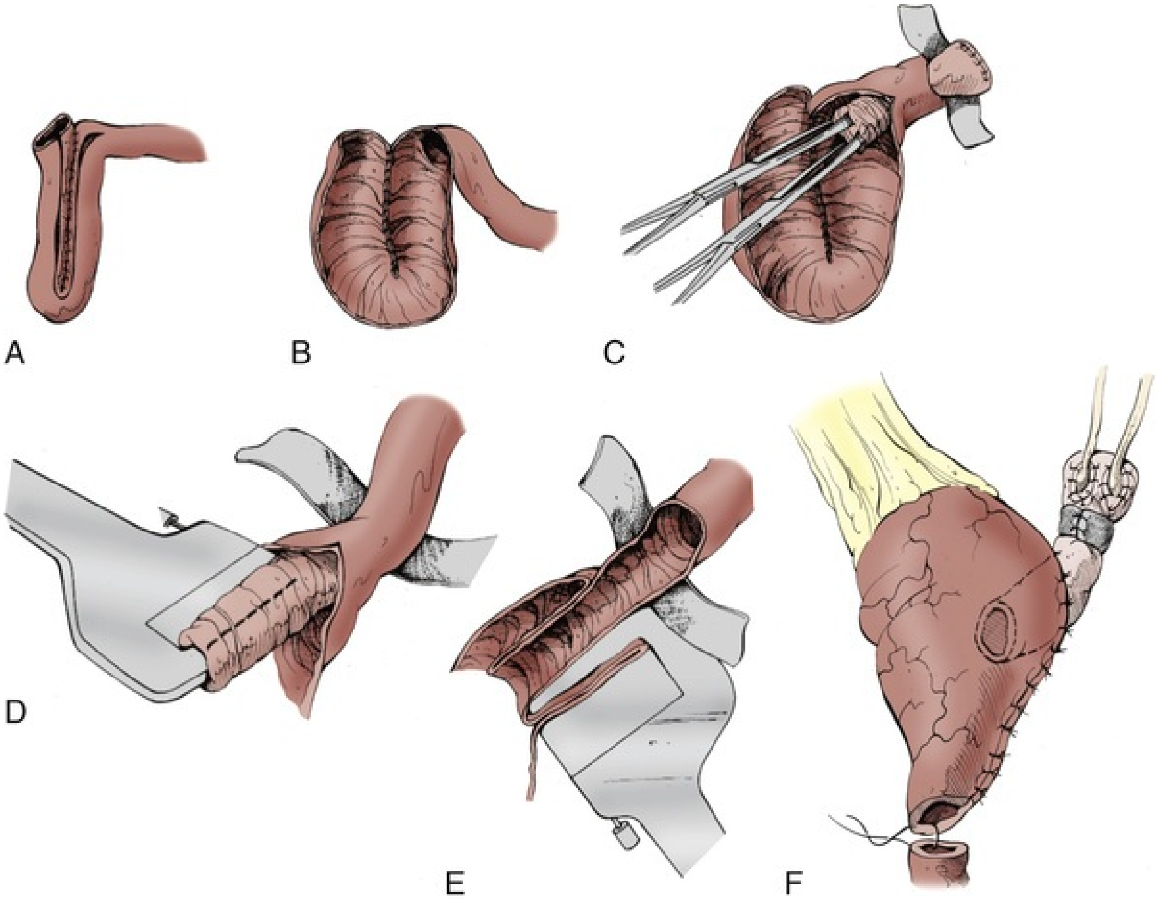

FIG. 141.6 Construction of the Kock ileal reservoir. (A) A total of 61 cm of terminal ileum is isolated. Two 22-cm segments are placed in a *U* configuration and opened adjacent to the mesentery. The more proximal 17-cm segment of ileum will be used to make the afferent intussuscepted nipple valve. (B) The posterior wall of the reservoir is then formed by joining the medial portions of the *U* with a continuous running suture. (C) A 5- to 7-cm antireflux valve is made by removing the mesentery under that

segment and then intussuscepting the afferent limb with the use of Allis forceps clamps. (D) The afferent limb is fixed with two rows of staples placed within the leaves of the valve. (E) The valve is then fixed to the back wall from outside the reservoir with additional surgical staples. (F) After completion of the nipple valve, the reservoir is completed by folding the ileum on itself and closing it, leaving the most dependent end of the suture line open for the urethral anastomosis.

Serous-Lined Extramural Tunnel

Abol-Enein and Ghoneim (1993, 1994) demonstrated that an effective antireflux mechanism could be made by bringing the ureters into a reservoir through extramural serous-lined tunnels. These authors believed that the construction of an extramural serous-lined tunnel provides several advantages. Metallic staples or synthetic materials are not required. The serous-lined tunnel protects the implanted portion of the ureter from exposure to urine so that sound healing without scarring is ensured. Moreover, a relatively short segment of bowel is used, and the procedure is versatile and not technically difficult. The authors updated their excellent results in 450 patients with this technique and demonstrated that the serous-lined extramural tunnel is an effective and durable antireflux technique, with more than 93% of patients having unidirectional, unobstructed urinary flow (Abol-Enein and Ghoneim, 2001).

A 40-cm ileal segment is isolated from the distal ileum and arranged in a W configuration. The antimesenteric border of the isolated intestine is opened, and the edges of the medial flaps are joined with a running absorbable suture. On either side, the serosal surface of the two lateral flaps are joined by a seromuscular continuous suture of silk (3-0). This forms two serous-lined intestinal troughs. Each ureter is laid down in its corresponding trough. A mucosa-to-mucosa anastomosis is performed with the spatulated ureter and the intestinal mucosa at the distal end of the trough. The mucosal edges on each side are then approximated over the reimplanted ureter. The anterior wall of the pouch is then closed in a side-to-side fashion. The suture line of the most dependent portion of the pouch close to the urethral stump is reopened to make a hole that will be anastomosed to the urethra (Fig. 141.7).

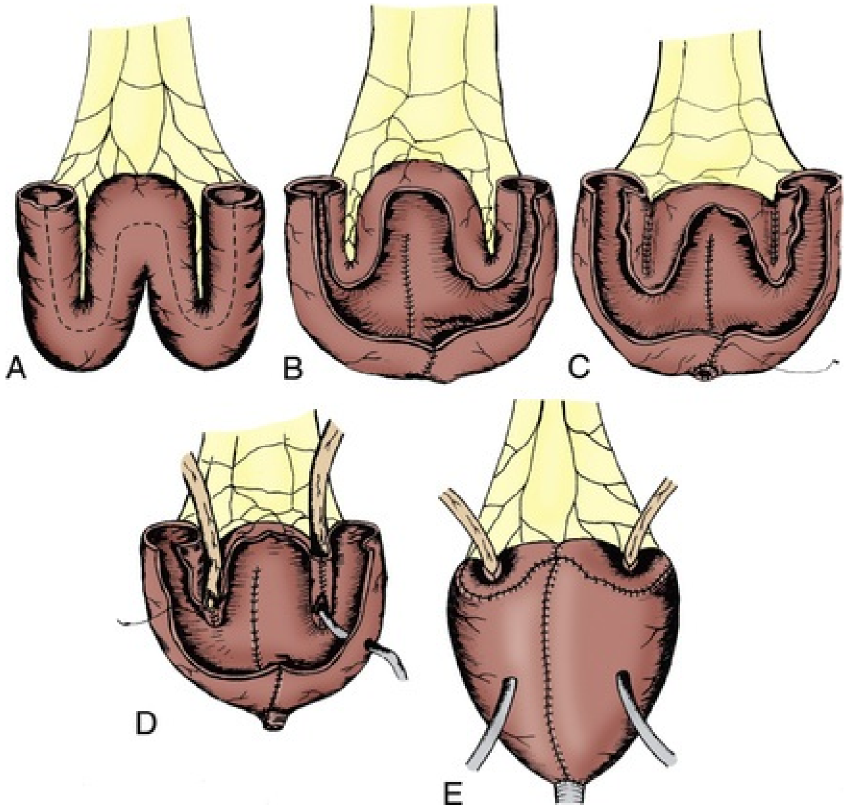

FIG. 141.7 Construction of the serous-lined, extramural ileal neobladder (Ghoneim). (A) A 40-cm segment of ileum is isolated and fashioned into a *W* configuration. (B) The ileum is opened along the antimesenteric border for the entire length. (C) The incised mucosa is joined in the middle with a running suture. The two lateral ileal flaps are joined by a seromuscular continuous suture to make the backing for the serous-lined ureteral tunnels. (D) The spatulated ureters are laid into each trough, anastomosed to the intestinal mucosa, and stented. The tunnel is then closed over the implanted ureter. (E) The anterior wall of the reservoir is formed by folding the ileum side to side. The reservoir is then anastomosed to the urethra.

Others have reported favorable results with this technique (Papadopoulos and Jacobsen, 2001). A modification of this orthotopic substitute with a serous-lined extramural ureteral reimplantation technique was also reported by Kato et al. (2001) with similar results. The primary disadvantage of this technique is the requirement for long ureteral length, inability to accommodate dilated ureters, and a possibly increased risk for ureteral strictures. More than 1600 patients have now undergone the serous-lined antireflux ureteral implantation procedure. Follow-up of 400 patients of minimum 10 years showed preservation of the upper tract in 90% of them (Hautmann et al., 2015).

Ileal Neobladder (Hautmann Pouch)

Hautmann (2010) developed the Hautmann pouch ileal neobladder (Hautmann et al., 2010, 2011). This neobladder is a large-capacity, spheric (W configuration) ileal reservoir that is constructed in an attempt to optimize initial volume and potentially reduce nighttime incontinence. A segment of terminal ileum of approximately 70 cm is selected. The bowel is reconstituted, and the mesenteric trap is closed. The ileal section that reaches the urethra most easily is identified and marked with a traction suture along the antimesenteric border. The isolated bowel segment is then arranged in either an M or W shape and is opened along the antimesenteric border except for a 5-cm section along the traction suture where the incision is curved to make a U-shaped flap.

The four limbs of the M or W are then sutured to one another with a running absorbable suture. A small full-thickness segment of bowel is excised in the site for the urethral anastomosis, which is then performed with the sutures tied from inside the neobladder. Once the ileal neobladder is situated in the pelvis and the urethral sutures are tied, the ureters are implanted from inside the neobladder through a small incision in the ileum at a convenient site. The remaining portion of the anterior wall is then closed with a running absorbable suture (Fig. 141.8).

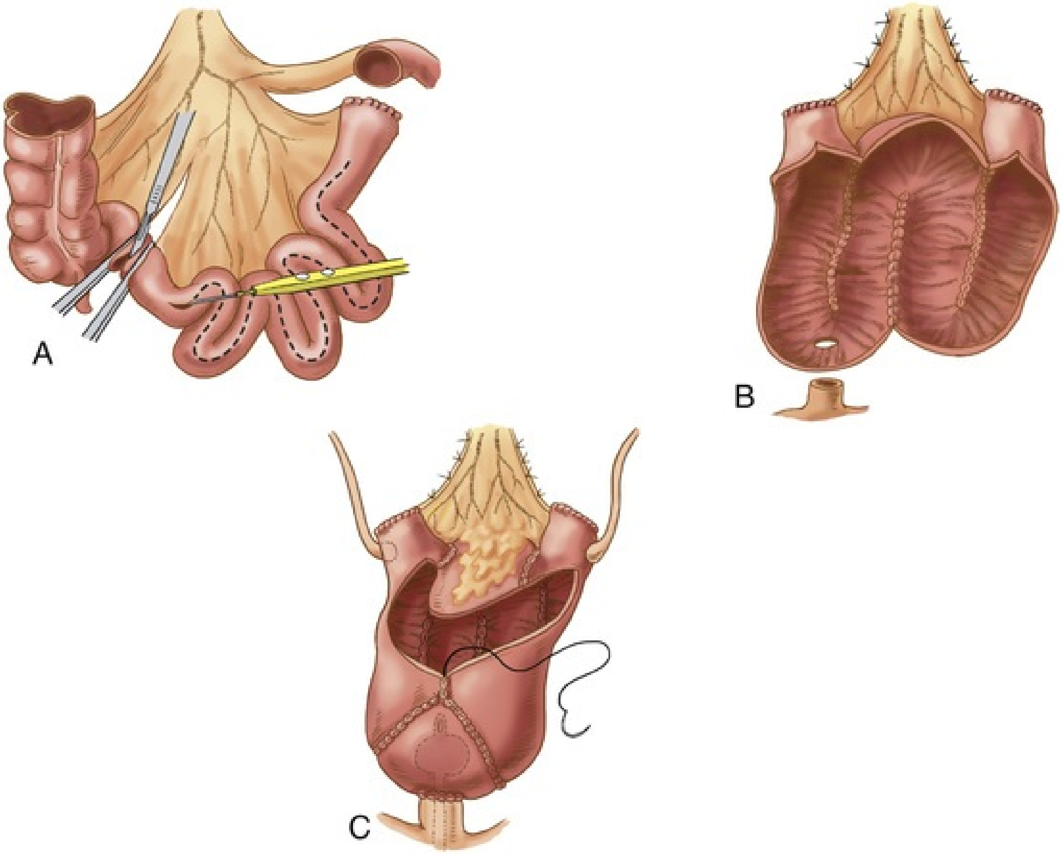

FIG. 141.8 Construction of the modified Hautmann ileal neobladder. (A) A 70-cm portion of terminal ileum is selected. The isolated segment of ileum is incised on the antimesenteric border, leaving approximately 5 cm on each end intact. (B) The ileum is arranged into a *W* configuration with the four limbs sutured to one another. (C) After a buttonhole of ileum is removed on an antimesenteric dependent portion of the ileum, the urethral anastomosis is performed. The ureteral anastomoses are performed by direct implantation, either end-to-side *(as shown)* or directly to the open ends of the two segments, and are stented. The reservoir is then closed in a side-to-side manner.

Initially Hautmann used an antireflux ureteral anastomosis as described by Le Duc et al. (Le Duc et al., 1987). However, ureteroileal strictures were fairly common, and beginning in 1997 he modified this technique and now uses a freely refluxing, open end-to-side anastomosis implanted into short tubularized segments at each end of the W. This resulted in a decrease in the risk for ureteroileal stenosis from 9.5% to 1% (Hautmann, 2001; Hautmann et al., 2006, 2017).

This pouch has a larger initial capacity than the Studer pouch, which may assist in earlier continence. However, it may also result in an increased incidence of late urinary retention and increased electrolyte reabsorption from the pouch.

Sevin et al. (2004) reported a modified Hautmann ileal neobladder in which only 40 cm of ileum is used to reduce these potential issues with acceptable clinical outcomes. The classic configuration of the pouch also could not accommodate short ureters, but in the revised technique shown, one or both ends of the W can be left long to anastomose to one or both shortened ureters (Hollowell et al., 2000).

Studer Pouch

The ileal bladder substitute as initially described by Studer et al. (1989, 1996) used a long, afferent, isoperistaltic, tubular ileal segment. It is believed that the long segment functionally prevents vesicoureteral reflux when the patient voids by Valsalva maneuver. It is straightforward to construct and has become one of the most popular forms of orthotopic diversion in the United States. The advantages of this bladder substitute include simplicity of construction, lack of a requirement for surgical staples, and ability to accommodate short ureters. The reservoir portion uses the optimal double-folded U configuration as originally described by Kock et al. (1989). Studer et al. (2006) reported on 480 of these procedures performed from 1985 to 2005 with excellent long-term results in terms of continence, preservation of renal function, and a ureteroileal stricture rate of less than 3%. The original description used a 20-cm afferent segment, with 40 cm used for the reservoir. In more recent years, Studer et al. (2006) have advocated using a somewhat shorter afferent ileal segment, with similar results. Their group has reported continued excellent functional outcomes with long-term follow-up, with satisfactory urinary continence, the vast majority able to void without self-catheterization, and excellent preservation of renal function up to 20 years. A total of 81 complications were reported in 42 of the 200 patients (21%) 10 years or longer after radical cystectomy, with pyelonephritis being the most frequent cause (Furrer et al., 2016).

The terminal portion of the ileum (54 to 56 cm long) is isolated approximately 15 to 20 cm proximal to the ileocecal valve. The distal mesenteric division is made along the avascular plane between the ileocolic artery and terminal branches of the superior mesenteric artery. The proximal mesenteric division, however, is short and provides a broad vascular blood supply to the reservoir. In addition, a small window of mesentery and 5 cm of small bowel proximal to the overall ileal segment are discarded, ensuring mobility to the pouch and small bowel anastomosis. Bowel anastomosis is performed using staplers.

The pouch is created from 40 to 44 cm of distal ileum with each limb of the U measuring 20 to 22 cm and a proximal 15-cm segment of ileum used as the afferent limb. If ureteral length is short or compromised, a longer afferent ileal segment (proximal ileum) may be used. The proximal end of the isolated afferent ileal segment is closed with absorbable sutures. The isolated ileal segment is opened about 2 cm away from the mesentery, and the incised ileal mucosa is then oversewn with two layers of a running 3-0 polyglycolic acid suture (Fig. 141.9).

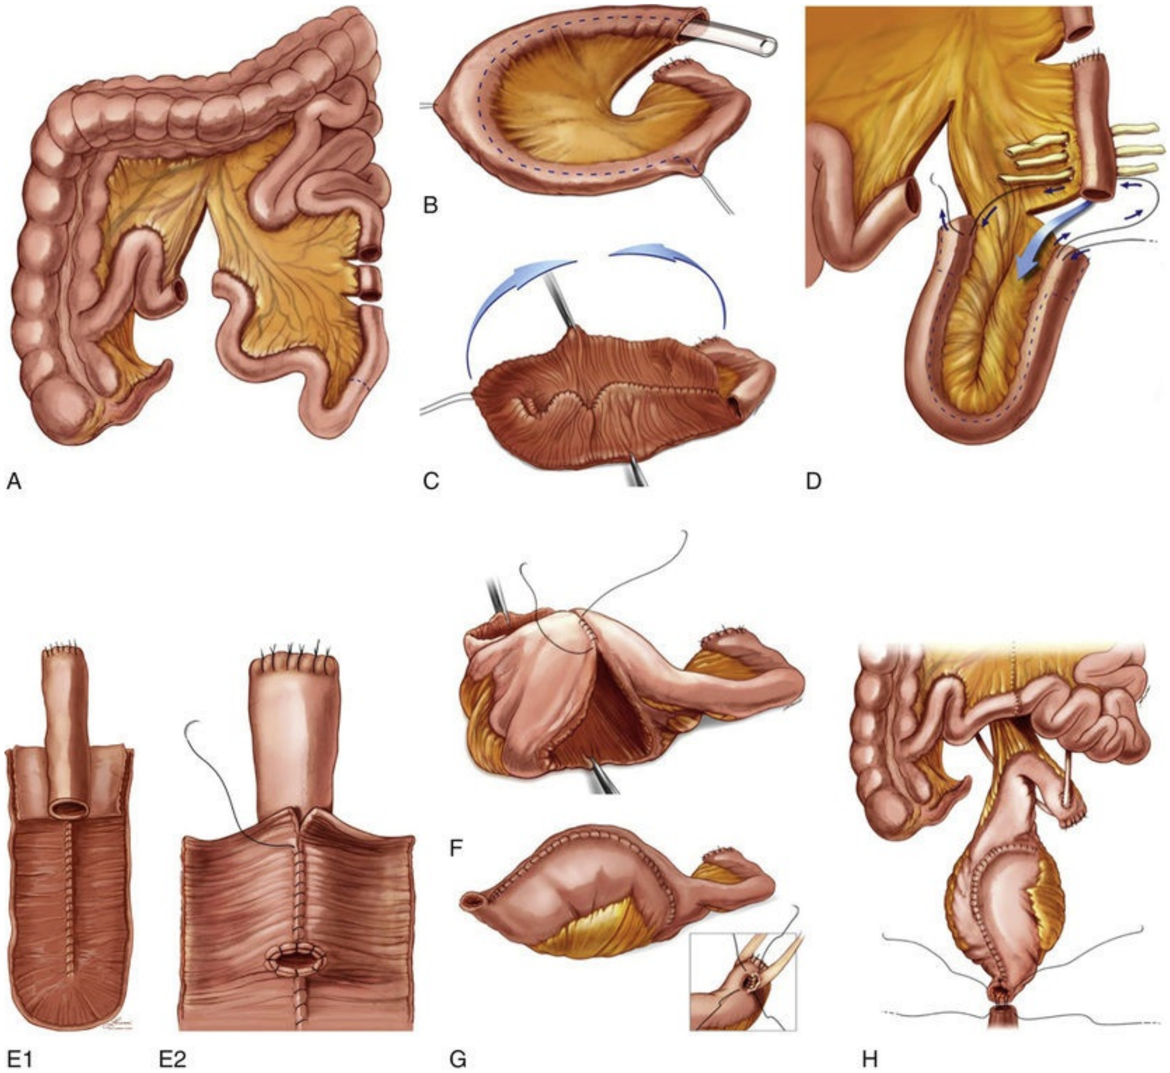

FIG. 141.9 Construction of the modified Studer neobladder (with T pouch modification). (A) Designated segments of terminal ileum for construction of the orthotopic Studer pouch ileal neobladder. Note that the distal mesenteric division is made between the ileocolic and terminal branches of the superior mesenteric artery, which extends into the avascular plane of the mesentery. Two 22-cm lengths make the reservoir and a proximal 10- to 12-cm length for the afferent limb. Proximal to this, a 5-cm segment of

small bowel is discarded to allow mobility to the pouch and small bowel anastomosis and avoid deep incision into the mesentery at that location, which could compromise vascular supply to the pouch. (B) The 44-cm length is opened along the medial mesentery. (C) The two 22-cm segments are joined in a *U* shape and then closed in the opposite direction, sewing each suture line with running 3-0 polyglycolic acid sutures. The reservoir is then folding it in half in the opposite direction to which it was opened. (D) Construction of the antireflux T pouch modification. The afferent limb segment is separated from the reservoir segment. The butt end of the afferent limb is closed. The *dotted line* depicts the incision line on the 44-cm segment to detubularize the portion for the reservoir. The incision is, diverted laterally near the two ends to form the flap for the afferent limb tunnel. The two ends of the reservoir are closed. Mesenteric windows are opened between the vascular arcades adjacent to the serosa of the afferent limb, and a piece of small Penrose drain is placed through each mesenteric window. The serosa of the two limbs of the reservoir is brought together through the windows with interrupted 3-0 silk sutures to fix the backing of the tunneled afferent limb. Multiple sutures are placed through each window to secure the fixation while maintaining good blood supply to the afferent limb. (E1) The afferent limb is fixed in place. (E2) The flaps of the reservoir are closed over the top of the fixed distal afferent limb, and the opening is matured into the reservoir. (F) For either the Studer or T pouch, the reservoir is folded in half, and the anterior wall is closed with a two-layer 3-0 polyglycolic acid running suture. A fingerbreadth opening can be left in the most dependent end of the suture line for the urethral anastomosis, or, alternatively, a separate buttonhole opening can be made in the reservoir. (G) Each ureter is spatulated, and an end-to-side ureteroileal anastomosis is performed using interrupted 4-0 polyglycolic acid sutures and stents placed. (H) The reservoir is anastomosed to the urethra using the previously placed urethral sutures. (Copyright 2012 Laramie Studio. Used with permission.)

T Pouch Modification

In an effort to preserve an antireflux mechanism but avoid the potential long-term complications seen with the Kock nipple valve, and to allow for more flexibility in managing the ureters, Stein and Skinner developed the T pouch with construction of an antirefluxing afferent limb as a modification of Ghoneim and Abol-Enein's serous-lined ureteral tunnel. They reported their results with intermediate follow-up of 209 patients (Stein et al., 2004; Stein and Skinner, 2006). The ileum is divided between the proximal afferent ileal segment and the 44-cm segment, and the antireflux mechanism is created by anchoring the distal 3 to 4 cm of the 15-cm afferent ileal segment into the serosal-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments. Mesenteric windows of Deaver are opened between the vascular arcades on the T limb. A series of 3-0 silk sutures is then used to approximate the serosa of the two adjacent 22-cm ileal segments at the base of the U, with the sutures being passed through the previously opened windows of Deaver to anchor the afferent limb (see Fig. 141.9D, E1, and E2). Initial descriptions of the T pouch included tapering the distal portion of the afferent segment after it had been fixed into the tunnel to decrease its diameter and decrease the risk for reflux. However, these efforts appeared to be associated with occasional late stenosis of the end of the afferent valve. In 2004, the author (E.C.S.) stopped tapering the distal afferent limb with improved results.

When the incision in the U limb of reservoir reaches the level of the afferent ostium, it is extended directly lateral to the antimesenteric border of the ileum and carried upward (cephalad) to the base of the ileal segment. This incision provides wide flaps of ileum that are brought over the afferent ileal segment and sutured in two layers to create the antireflux mechanism in a flap-valve technique. An interrupted mucosa-to-mucosa anastomosis is then performed between the ostium of the afferent ileal limb and the incised intestinal ileal flaps with 3-0 polyglycolic acid sutures (see Fig. 141.9E2). The rest of the neobladder is constructed in the same fashion as the Studer pouch. Ureteral stents are internalized into the pouch and sewn to the indwelling urethral catheter, and no suprapubic tube is used.

Colon and Ileocolic Pouches

Orthotopic neobladders constructed completely of colon are a good option for patients with multiple previous small bowel resections or who have diseased ileum. Colon segments are less distensible than ileal segments and may be more likely to produce higher-pressure waves causing incontinence (Khafagy et al., 2006). As a consequence, initial volume should be larger than for an ileal pouch. Combined colon and ileal segments can mitigate this problem.

Orthotopic Mainz Pouch (Mainz III)

The Mainz (“mixed augmented ileum and zecum”) pouch was initially described as a continent catheterizable reservoir that was subsequently modified into an orthotopic neobladder (Eisenberger et al., 1999; Thuroff et al., 1986). A 10- to 15-cm segment of cecum, in continuity with a 20- to 30-cm segment of ileum, is isolated. An ascending ileocolostomy is performed. The entire segment of bowel is opened along the antimesenteric border, sacrificing the ileocecal valve. The bowel is placed in a W configuration, with the first limb of the W made from cecum and the other limbs made from the ileum. The adjacent three limbs are sutured together with an absorbable suture, forming the posterior plate of the reservoir. At the cephalad portion of the cecum, tunneled ureterocolonic anastomosis is performed. A buttonhole incision is made in the cecum at the base of the reservoir, and a ureterocolonic anastomosis is performed. After this, the reservoir is closed side to side with absorbable suture (Fig. 141.10).

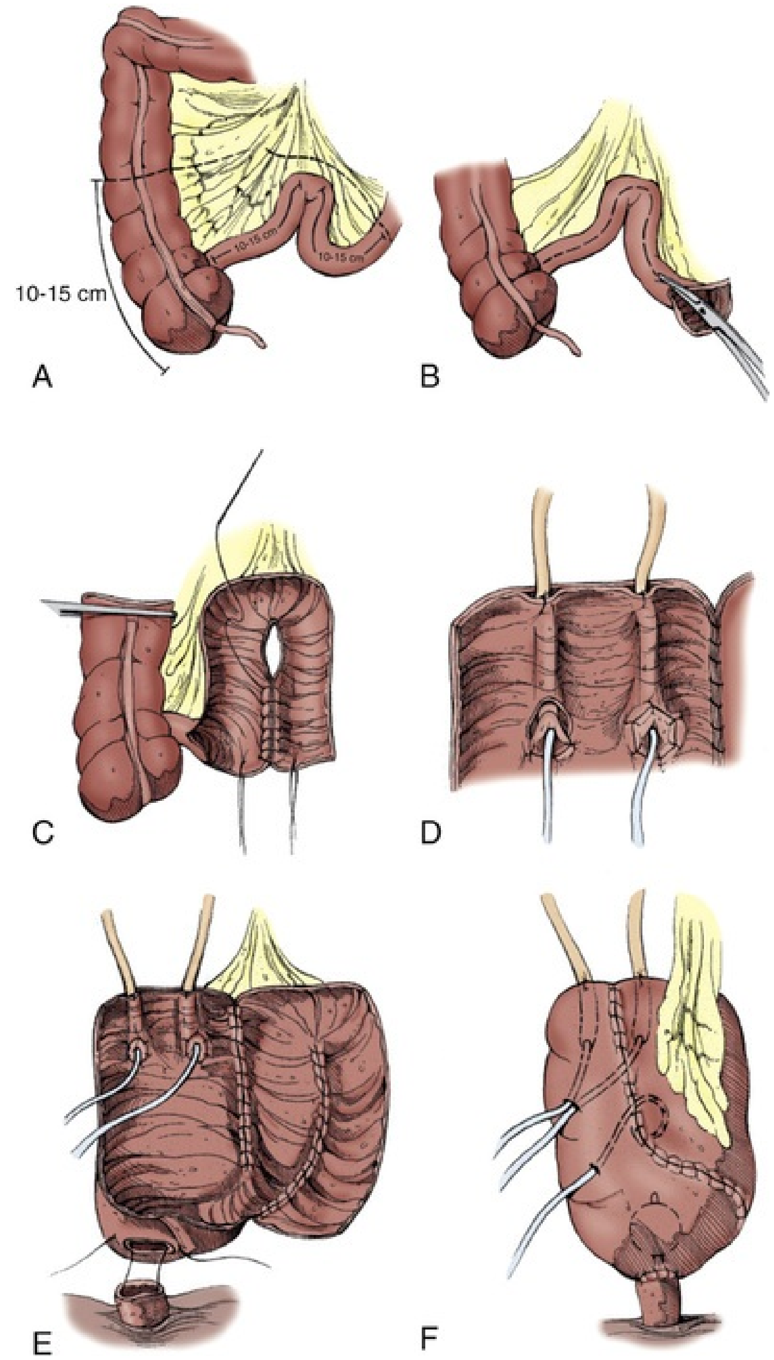

FIG. 141.10 Construction of the Mainz ileocolonic orthotopic reservoir. (A) An isolated 10 to 15 cm of cecum in continuity with 20 to 30 cm of ileum are isolated. (B) The entire bowel segment is opened along the antimesenteric border. An appendectomy is performed. (C) The posterior reservoir is closed by joining the opposing three limbs together with a continuous running suture. (D) An antireflux implantation of the ureters through a submucosal tunnel is performed and stented. (E) A buttonhole incision in the dependent portion of the cecum is made to provide for the urethral anastomosis. (F) The reservoir is closed side to side with a cystostomy tube and the stents exiting.

Right Colon Pouch

An orthotopic substitute using the right colon without ileum has been reported (Goldwasser, 1995; Goldwasser et al., 1986; Månsson and Colleen, 1990; Månsson et al., 2003). The entire right colon and cecum are isolated, and a transverse ileocolonic anastomosis is performed to provide bowel continuity. The ileal stump at the ileocecal valve is closed with a running absorbable suture. The colonic segment is then opened along the anterior taenia, leaving the proximal 2 to 3 inches of cecum intact. An appendectomy is performed, and the ureters are implanted in an antireflux fashion within the reservoir. The colon is then folded in a Heineke-Mikulicz manner and closed with a running absorbable suture. The ureterocolonic anastomosis is then performed.

Sigmoid Pouch

Patients who are candidates for radical cystectomy often have a redundant sigmoid colon, which is readily available for use. The only concern is the potential compromise of the vasculature of the distal colon segment because of interruption of branches of the internal iliac artery during the cystectomy. It is important, therefore, to maintain as much of the vascular supply to both ends of the bowel anastomosis as possible. Some patients will complain of frequent stools or rectal urgency for a period after sigmoid colectomy.

The use of the sigmoid in construction of an orthotopic substitute was initially described by Reddy and Lange (Fig. 141.11). A 35-cm portion of descending colon and sigmoid is isolated and arranged in a U configuration on the basis of the inferior mesenteric artery. The medial taenia of the U is incised down to an area just short of the urethral anastomosis. The incised medial limbs of the U are then brought together with an absorbable suture. Ureteral implantation is performed in a tunnel antireflux fashion. A small button of colon is removed from the most dependent portion of the reservoir, and the urethroenteric anastomosis is performed. The reservoir is then closed side to side (Reddy and Lange, 1987).

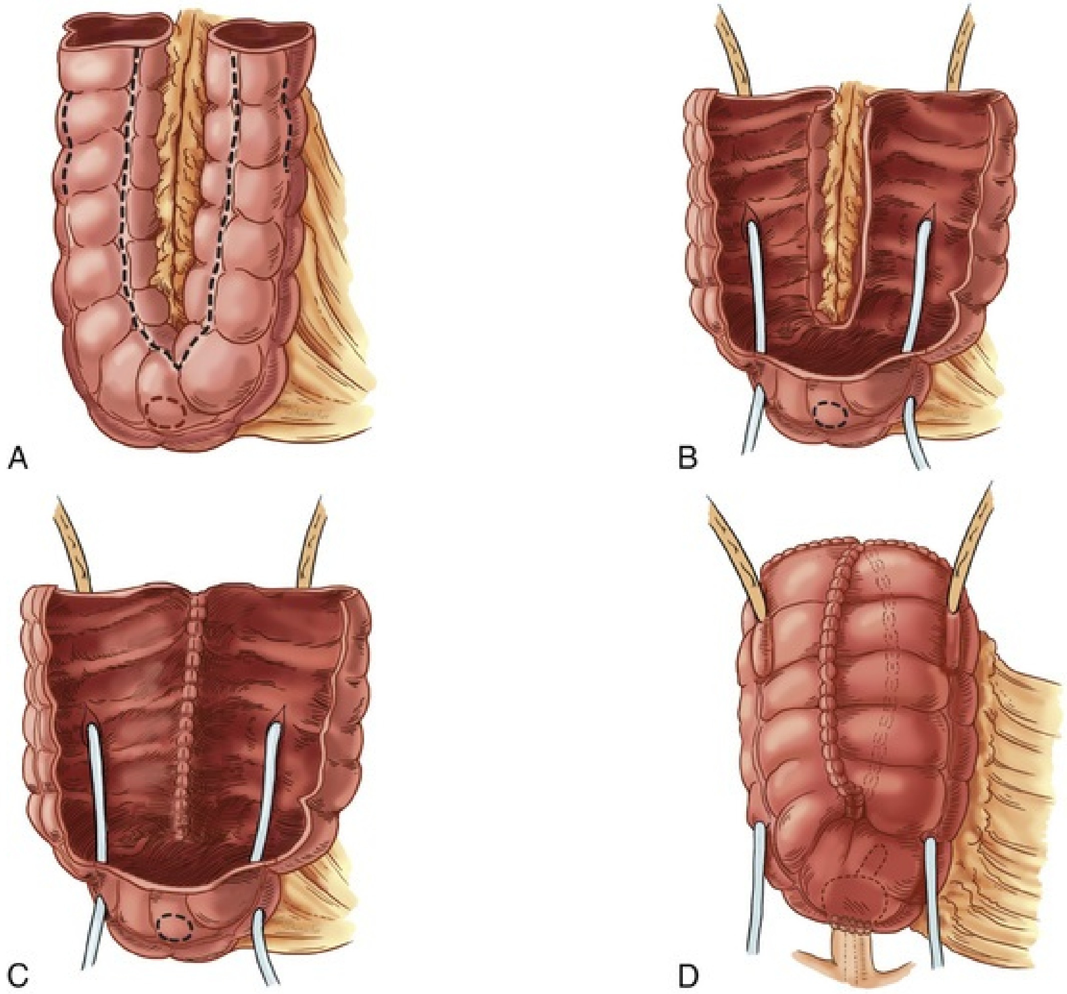

FIG. 141.11 Construction of the sigmoid (Reddy) neobladder. (A) A 35-cm segment of descending and sigmoid colon is isolated and folded into a U shape. (B) The colon is incised along the medial taenia down to a point a few centimeters short of the entire colon. A buttonhole is made in the caudal portion of the colon that is later anastomosed to the urethra. (C) The medial portions of the U are sewn together, and a tunneled ureterocolonic anastomosis is performed. (D) The colonic pouch is closed by folding the reservoir side to side, and it is anastomosed to the urethra.

DaPozzo et al. (1994) reported a modification of this technique in which the entire bowel is detubularized and then folded in a Heineke-Mikulicz fashion to provide a more spheric reservoir.

Padua Pouch (Vesica Ileale Padovana)

The Padua or VIP pouch (“vesica ileale padovana”) uses a detubularized ileal segment for neobladder configuration incorporating two layers of folding and suturing of the posterior plate with subsequent closure of the anterior neobladder wall to create a spherical anatomic bladder. The pouch is constructed from about 42 cm of distal ileum, approximately 20 cm proximal to the ileocecal valve. The optimal point of the selected bowel loop for the urethral anastomosis is identified about 12 to 14 cm proximally to the distal ileal end, after ensuring it reaches the urethral stump without tension. This is usually in the most dependent part of the neobladder. The proximal half of the loop will configure the left base, and the dome of the ileal segments is utilized to tailor the neobladder. Ureters are spatulated and passed through the posterior aspect of the neobladder. Ureteroileal anastomoses are performed according to Le Duc/Camey technique with 4-0 Monocryl interrupted sutures and stented. Finally, the anterior aspect of the neobladder is hand-sewn with two sero-serous running sutures (Fig. 141.12).

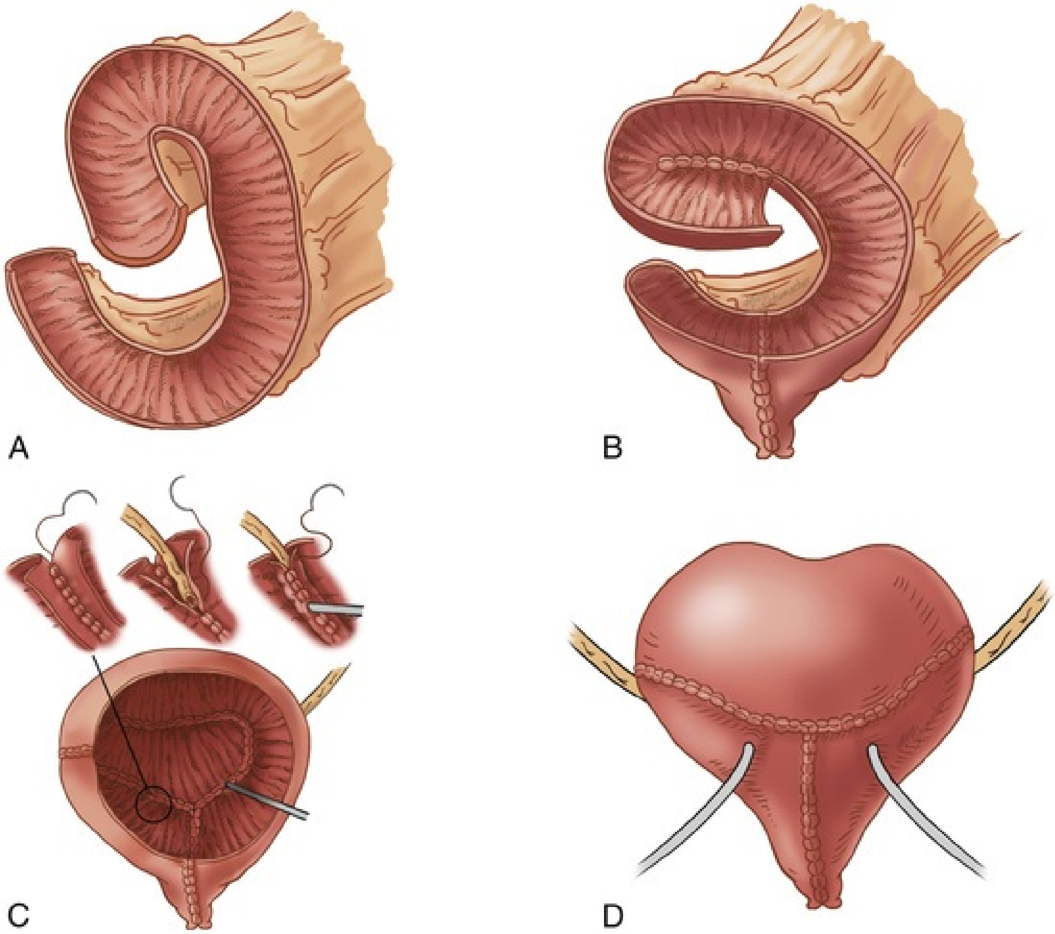

FIG. 141.12 Padua pouch (“vesica ileale padovana”). (A) A 42-cm segment of distal ileum is isolated and opened along its entire length. (B) An opening is made in the most dependent part of the segment for the urethral anastomosis, about 12 to 14 cm from the distal end of the segment. The anterior and posterior walls are sewn to create a funneled

bladder neck. The ileum is formed into a spiral shape *(as shown),* and the back wall is sutured with running absorbable sutures. (C) Before completing the posterior edge, the ureters are spatulated and passed through the posterior aspect of the neobladder and anastomosed according to Le Duc/Camey technique with 4-0 Monocryl interrupted sutures and stented. (D) The anterior aspect of the neobladder is folded together and sewn with two sero-serous running sutures. The ureteral stents are exteriorized.

Simone et al. recently reported their experience performing this technique robotically and completely intracorporeally in 45 patients with excellent functional results (Simone et al., 2018). Overall 30-day complication rates were 44.4%, and 2-year daytime and nighttime continence rates were 73.3% and 55.5%, respectively (Simone et al., 2018).

Use of Minimally Invasive Techniques for Orthotopic Diversion

Over the past 15 years, a number of surgeons have performed cystectomy using laparoscopic or robotic-assisted techniques (Gill et al., 2002; Pruthi and Wallen, 2008; Wang et al., 2008; Yuh et al., 2008). Initial attempts to perform the diversion completely intracorporeally were fraught with difficulty, and the procedure was performed with extracorporeal construction after removal of the bladder through a small midline incision (Haber et al., 2008). This allowed construction of continent diversions, both cutaneous and orthotopic. The Studer ileal neobladder has been the most popular because of ease of mobilization of the segment and simpler bowel anastomosis with a low abdominal incision. In the case of orthotopic neobladders, some authors reestablish the pneumoperitoneum and redock the robot to complete the urethral anastomosis. Others perform the anastomosis in an open fashion (Pruthi and Wallen, 2008).

Postoperative recovery in most series has only been modestly improved compared with open series, with longer operative times but decreased blood loss. Some series have reported reduced ileus and shorter hospital stay (Haber et al., 2008; Huang et al., 2008; Nix et al., 2010; Ng et al., 2010; Wang et al., 2008), but these were generally selected patients. Other unselected large series have shown that postoperative complications were equivalent or even increased compared with open series (Parekh et al., 2013; Raza et al., 2013; Yuh et al., 2012). **A randomized single-institution trial confirmed longer operative time and less blood loss, but no difference in other complications or short-term**

outcomes (Bochner et al., 2015). A multi-institutional prospective randomized noninferiority trial accrued 302 evaluable patients and found longer surgery time, lower blood loss and transfusion rates, and 1 day shorter average length of stay (6 vs. 7 days) for patients undergoing robotic-assisted surgery, with no difference in progression-free survival at 2 years. They also found no difference in major early complications or quality of life between the two arms (Parekh et al., 2018).

With increased robotic proficiency, several centers have gained experience in construction of the neobladder intracorporeally (Dason et al., 2018; Goh et al., 2012, Hussein et al., 2018). This remains a technically difficult procedure, even in the hands of surgeons with extensive robotic experience. The prospect of prolonged operation times and steep learning curves for similar length of stay and higher costs necessitate that these procedures be performed in centers of excellence with highly specialized robotic skills to facilitate superior outcomes. There is a lack of studies with comparable functional, quality-of-life and long-term outcomes of intracorporeal diversion techniques. Robotic cystectomy and urinary diversion are covered extensively in other chapters.

Results and Complications of Orthotopic Urinary Diversion

Early and Late Complications

A complete discussion of the complications of radical cystectomy and diversion is outside the scope of this chapter. These complications could have detrimental effects on health and quality of life, and they may even be life-threatening. Long-term follow-up of patients with urinary diversion is of utmost importance as many diversion-related complications occur years after surgery (Amini and Djaladat, 2017; Ali-El-Dein et al., 2008; Hautmann et al., 2010, 2011; Konety et al., 2006; Quek et al., 2006; Shabsigh et al., 2009). **Early complications include bleeding, thrombotic events, infection, and cardiovascular and pulmonary complications, which are not directly related to the urinary diversion** and do not appear to be different in patients undergoing different types of diversion. Gastrointestinal complications, particularly ileus, are also common after cystectomy and are at least partially related to the need for a bowel anastomosis, which is common to all types of diversion (Bazargani et al., 2018). Similarly, urine leak and ureteral complications are possible with any type of diversion. A number of authors have shown that the overall rate of complications, hospital stay, and reoperation rates are not increased by use of continent diversion compared with ileal conduit diversion (Benson et al., 1992; Gburek et al., 1998; Parekh et al., 2000a).

Urine leaks may be more common in continent diversion than in conduits because of the long suture lines, but with good catheter drainage and properly managed stents and drains, these usually resolve with observation alone as long as a urinoma does not form. **If a patient has an undrained leak, an attempt at percutaneous drainage and/or bilateral nephrostomy tube placement is preferable to open surgical repair.** The latter is extremely difficult during the first few weeks after the initial surgery and is likely to be complicated by enterotomies and a risk for fistula formation. In our experience, less than 5% of patients require some sort of percutaneous drain or nephrostomy tube placement during the early postoperative period to manage these problems.

Both early and late complications may also be influenced by other factors such as prior radiation therapy, diabetes, and other comorbidities. Late complications are also influenced by tumor recurrence and the use of adjuvant or salvage systemic chemotherapy or radiation, and these causes may be difficult to separate out from causes related to the surgery. Late complications not directly related to the diversion include bowel obstruction, ventral hernia, thrombotic events, and cardiovascular problems common to patients in this age group. Hautmann et al. (2011) made the point that most late complications increase with time and are best described using Kaplan-Meier curves rather than as simple percentages. Ventral hernias are quite common and may be in part related to the need for increased abdominal pressure to empty the neobladder. The poor fascial strength associated with advanced age and smoking undoubtedly contributes to this risk as well.

The primary late complications of orthotopic diversion that are directly related to the diversion itself include incontinence, urinary retention, urinary tract infection, ureteroileal or afferent limb obstruction, urethral stricture, upper tract and pouch stones, vaginal fistula, and pouch rupture. Most of these can be managed by endoscopic procedures and rarely require open surgical revision (Amini and Djaladat, 2017; Hautmann et al., 2011; Rowland, 1995).

Although symptomatic urinary infections do occur, asymptomatic colonization of the neobladder with bacteria is also very common, particularly if the patient is on intermittent self-catheterization (Suriano et al., 2008). Incidence of urinary tract infection is comparable between conduit and continent diversions (Al Hussein et al., 2015). Wood et al. (2003) reported on 66 patients undergoing orthotopic refluxing ileal neobladder, 11 of whom (17%) were performing intermittent self-catheterization. Positive urine cultures were found in 39%. Symptomatic urinary tract infections are uncommon after the initial 90-day postoperative period. Hautmann et al. (2011) found a cumulative risk for febrile infections of only 5.7% in 923 patients undergoing ileal neobladder with a 72-month median follow-up. Infections were most common in the first year and occurred in 13.6% of those with poor emptying compared with only 3.4% in those who emptied well (Hautmann et al., 2011; Steven and Poulsen, 2000). Bowel mucosa in contrast with urothelium is not capable of inhibiting bacterial proliferation. Treatment of asymptomatic bacteriuria is likely to simply encourage development of resistant organisms and is often unnecessary. However, patients with symptomatic infection and those with positive cultures for *Proteus* or *Pseudomonas* require treatment because these infections may result in renal function deterioration (McDougal, 1986). **A patient who develops**

a febrile urinary infection or pyelonephritis after the initial few months should be evaluated for possible upper tract obstruction, stones, or incomplete emptying. Daily suppressive antibiotics with nitrofurantoin, sulfa, or methenamine may be helpful in the patient with recurrent symptomatic urinary infections in whom an anatomic cause has been ruled out.

Pouch perforation is rare because outlet resistance is usually low. The risk may be increased in patients who have had previous radiation therapy or are in chronic retention. It is a potentially life-threatening complication when it occurs. Patients with a perforation typically have acute abdominal pain and distention, often with signs of sepsis. A cystogram is usually diagnostic. If the patient is stable, conservative management with catheter drainage with or without percutaneous drains can be considered (Hautmann et al., 2013; Månsson et al., 1997; Singh and Choong, 2004).

The rate of ureteroileal stricture is identical to that in ileal conduit diversion and is influenced by the type of anastomosis. **The direct end-to-side Leadbetter or the combined Wallace anastomoses with interrupted fine absorbable sutures have been shown to have the lowest risk for stricture, approximately 3% to 6%** (Hautmann et al., 2011, 2017; Pantuck et al., 2000)**. Obstruction from an antireflux valve has been seen in both hemi-Kock pouches and in the extraserosal tunneled afferent limb of the T pouch** (Stein et al., 1996, 2004). In a randomized clinical trial comparing refluxing and nonrefluxing ureteroenteric anastomosis, Shaaban et al. (2006) showed that nonrefluxing anastomoses are associated with a significantly higher rate of ureteral obstruction and subsequent renal function deterioration. Stricture usually occurs within a few months of surgery but can occur even after 10 years. Therefore, lifelong observation for ureteral stricture is imperative in patients with urinary diversion. Previous history of abdominal/pelvic irradiation has been postulated to increase the risk for ureteroenteric anastomosis; however, in a recent large series from the University of Southern California, multivariate logistic regression analysis did not show any correlation between ureteroenteric anastomosis stricture and history of perioperative radiation therapy. (Shah et al,. 2015). Surgical technique is the most important determining factor, and ureteroileal anastomosis should be performed using meticulous surgical techniques. Strictures may be clinically silent until the patient develops bilateral hydronephrosis or even renal failure. Diagnosis may be suspected on CT or ultrasonography and can be confirmed on retrograde pyelography or antegrade nephrostogram. **CT scans often will be misinterpreted by radiologists or urologists who are unfamiliar with the anatomy and/or the specific type of neobladder.** The obstructing antireflux segment may be managed by endoscopic incision of the valve mechanism. It can be technically challenging to find the afferent limb in some cases, and special techniques may be necessary to catheterize and incise it (Dunn et al., 2007). Although in selected cases endourologic techniques may be effective, overall success rate is much lower compared with open surgical repair, and the retreatment rate exceeds 50% (Schondorf et al., 2013).

Pouch stones were very commonly seen in the Kock neobladder because of the use of surgical staples to maintain the intussuscepted nipple valve, with the incidence increasing steadily with time (Stein et al., 1996). Stones have been rare in the Studer and Hautmann neobladders, which are made entirely with absorbable suture (Studer et al., 2006; Hautmann et al., 2011). Recently several authors have advocated use of a metal GIA stapler to speed up the construction of an ileal neobladder. In one such series of 50 patients, stones were found in 6% of patients with only a 20-month median follow-up (Barbalat et al., 2012; Fontana et al., 2004). A larger series of more than 600 patients who underwent a stapled form of Camey II found a 4.5% rate of stone formation at 5 years (Muto et al. 2016). It is predictable that the incidence of such stones will increase with more follow-up, and although they can be managed endoscopically this carries significant cost in both money and inconvenience for patients and may lead to further complications (Suriano et al., 2013).

Pouch-vaginal fistula is a unique complication of orthotopic neobladder in women that can be quite difficult to repair. The reported incidence in larger series is 5% to 10%, and the risk is increased if a portion of the anterior vaginal wall is excised along with the cystectomy specimen and in irradiated patients (Ali-El-Dein et al., 2008, 2013; Granberg et al., 2008; Rosenberg et al., 2018). **Prevention methods include vaginal-sparing techniques whenever it is safe from an oncologic standpoint, careful watertight closure of the vaginal cuff when it is opened, and placement of an omental flap** between the vagina and neobladder, secured to the perivaginal tissue on either side of the urethral anastomosis (Stein and Skinner, 2006). In the early postoperative period, any concern about vaginal urinary leakage should be evaluated with a lateral cystogram before removal of the catheter. Fistula should also be ruled out in any woman with persistent significant incontinence after the first few months of recovery. This is most easily done with a careful pelvic examination and with methylene blue instilled into the neobladder if necessary.

Beyond the initial few weeks, a pouch-vaginal fistula is unlikely to heal spontaneously or with catheter drainage or percutaneous nephrostomy tubes alone. Repair may be attempted transvaginally, although reported success varies (Ali-El-Dein and Ashamallah, 2013; Ali-El-Dein et al., 2008; Rosenberg et al., 2018; Rapp et al., 2004; Smith, 2005). Repair may ultimately require transabdominal exploration or even conversion to a cutaneous form of diversion.

Continence

The prevalence and severity of urinary incontinence may be influenced by a number of variables including age and gender of the patients, prior treatments (such as radiation or prostate surgery), surgical techniques, and surgeon experience. In addition, the definitions of continence, the method of data collection (e.g., retrospective chart review, telephone interview, or anonymous validated questionnaire), and the length and diligence of follow-up have varied tremendously among different reports (Clifford et al., 2016; Hautmann et al., 2013; Thuroff et al., 1996). Although there is general consensus that the ideal tool for studying functional outcomes is a validated patient-completed questionnaire, all the tools available today have significant drawbacks. The widely used Bladder Cancer Index (BCI) was developed to be applicable to all types of urinary diversion. It captures urinary leakage but not details such as the severity of incontinence or pad use (Gilbert et al., 2007). Only a few reports have used questionnaires such as these to evaluate neobladder patients (Ahmadi et al., 2013; Clifford et al., 2016; Jentzmik et al., 2012; Stein et al., 2009). **In summary, one should use caution in attempting to compare continence results from different series of patients with orthotopic diversion.** We have summarized results from some of the largest series in Tables 141.1 and 141.2.

IC, Intermittent catheterization to empty neobladder; *NA,* not available from report.

Common observations from series of patients undergoing orthotopic diversion include a gradual period of improvement in daytime continence over the first 6 to 12 months with a slower improvement in nighttime continence, even into the second year. In a pooled analysis of 2238 patients with various forms of orthotopic neobladder, daytime incontinence was reported in an average of only 13% of patients. Risk factors for daytime incontinence included advanced age of the patient (older than 65 years), use of colonic segments, and in some series lack of nerve-sparing techniques (Furrer et al., 2018; Kessler et al., 2004). Other series have identified hysterectomy in women and diabetes as a risk factor for poorer continence results (Ahmadi et al., 2013; Anderson et al., 2012; Steers, 2000). Ahmadi et al. (2013) reported on a group of 263 male patients without prior radiation who were at least 12 months out from a cystectomy and neobladder (Studer or T pouch). They were mailed the validated BCI with some additional questions designed to elucidate the types and degree of wetness of pads and the impact of mucous leak. The response rate was 68%, and 139 of 179 responders used pads at least sometimes, one-half of whom used them both in the day and at night. Forty-seven percent used pads in the day, with one-third of those using a small pad or minipad, and almost one-half found that the pad was usually dry or only slightly wet. Nighttime use was 72%, with most using a medium or heavy pad. Older age and diabetes correlated with poorer outcomes. The degree of incontinence and the urinary function scores on the BCI did not correlate well with the degree of bother from these symptoms, which was generally low (Ahmadi et al., 2013). We recently reported our continence outcomes in a prospective study of 188 male patients using a previously validated pictorial pad usage questionnaire. Daytime continence (defined as no pad use or pads "almost dry") peaked at 92% at 12 to 18 months postoperatively, and nighttime continence peaked at 51% at 18 to 36 months. Age older than 65 and diabetes were associated with poorer daytime continence. Only 10% of the patients reported clean intermittent catheterization at any time point in the postoperative period (Clifford et al., 2016).

Nighttime incontinence remains one of the most bothersome sequelae of neobladders, occurring in up to 50% of patients (see Tables 141.1 and 141.2) (Steers, 2000). Nocturnal incontinence results in part from the absence of neurologic feedback and sphincter detrusor reflex, and decreased sphincter tone and urethral sensitivity at night (Hugonnet et al., 1999). There is also physiologic nocturnal diuresis with an inability to concentrate the urine and a reversal of the normal antidiuretic effect of nighttime dehydration because of secretion of water by the bowel mucosa, which decreases with time (El-Bahnasawy et al., 2000). Instructing the patient to completely empty immediately before bedtime and to awaken two or three times with the assistance of an alarm clock if necessary may significantly reduce nighttime incontinence. We and others have observed that nighttime incontinence may improve as late as 24 months after surgery, and it is not a cause of major disturbance in quality of life for most patients (Elmajian et al., 1996; Granberg et al., 2008). A small study suggested that nightly desmopressin may help to reduce nocturia in patients with neobladders (Goldberg et al., 2014).

In women, preservation of the uterus may significantly affect the functional results of neobladder construction. Anderson et al. (2012) retrospectively reviewed 49 women who underwent cystectomy and neobladder procedures. Of the women, 31% had had a prior hysterectomy, 29% underwent hysterectomy at the time of cystectomy, and 40% had the uterus preserved. Women with the uterus preserved had better daytime continence. Ali-El-Dein et al. (2013) also reported on a small group of women who underwent uterus-sparing cystectomy with excellent short-term results. Studer also reported better functional outcomes in women undergoing preservation of the uterus and attempted nerve sparing (Gross et al., 2015). There is also suggestion that sexual function may be better preserved with this approach (Bhatt et al., 2006; El-Bahnasawy et al., 2011; Zippe et al., 2005).

Stein et al. (2009) previously reported results using the same questionnaire in 56 women. They found that 23% had frequent leakage or no control during the day and 34% during the night, with 61% requiring self-catheterization at least once daily (Stein et al., 2009, Bartsch et al., 2014). These results may more accurately reflect the true patient experience compared with reports from chart reviews.

The evaluation and management of urinary incontinence after orthotopic diversion should be delayed until the neobladder has had time to expand and patients' continence status has plateaued, which may take up to 12 to 18 months (Granberg et al., 2008; Grossfeld et al., 1996; Studer et al., 2006). Physical therapy with biofeedback focused on the pelvic floor muscles may help some patients attain initial continence (Johnson et al., 2017; Parekh et al., 2003). Urodynamic investigation may be indicated to ensure adequate capacity, without pressure waves, especially if colon is used for the neobladder. If reduction in maximal urethral closure or low Valsalva leak pressure is demonstrated, transurethral injection of bulking agents may be considered, but it has had only marginal results in our experience. Alternatively, in men an artificial urinary sphincter or urethral sling can be considered and may provide a more definitive treatment (Simma-Chiang et al., 2012). In women, although injection of urethral bulking agents provides a minimally invasive approach with some positive results (Tchetgen et al., 2000), it is best used for women with minimal symptoms of incontinence, with overall success rates below 50% and with less than optimally durable responses (Wilson et al., 2004). Newer agents that do not absorb over time may have improved results. Pubovaginal sling procedures for incontinence may be more effective than bulking agents in women with incontinence after orthotopic reconstruction; however, most of these patients will subsequently need to perform intermittent catheterization. It is important to note that one should avoid blind passage of needles or sling material into the pelvis in these patients because of a high risk for injury to the pouch or a loop of bowel stuck to the pubic symphysis. Use of infrapubic bone anchors or a prepubic approach may provide the safest surgical options (Quek et al., 2004).

Urinary Retention

Patients with incomplete emptying may have acute retention but more often have recurrent urinary infections or the new onset of overflow incontinence. They may also be discovered on routine follow-up with a palpable suprapubic mass, or distended reservoir or new-onset hydronephrosis on imaging. The development of retention may occur early but is often a late event, so the reported rates are heavily influenced by the length of follow-up of the series. Risk factors for urinary retention in patients with an orthotopic reservoir include the use of excessive intestinal length for the reservoir and the use of prostate-sparing technique (Ji et al., 2010; Steers, 2000; Stein et al., 2004; Steven and Poulsen, 2000). Some authors have suggested that the location of the urethral anastomosis in the neobladder may contribute to retention in men because of folding of the neobladder (Thurairaja and Studer, 2008), but our experience using the end of the suture line for the urethral anastomosis in an ileal neobladder has resulted in a similarly low incidence of retention (Ahmadi et al., 2013; Clifford et al., 2016; Stein et al., 2004). **Actual stricture of the neobladder-urethral anastomosis is rare.** In the series from Ulm with 923 patients and a 72-month median follow-up, such strictures developed in only 11 patients (1.2%) in the absence of tumor recurrence. More distal urethral strictures developed in an additional 8 patients (Hautmann et al., 2011).

Rectal or vaginal examination and cystoscopy should be performed in patients who develop retention to rule out a urethral anastomotic stricture or tumor recurrence. Urinary retention is best managed by intermittent self-catheterization (Steers, 2000), and pharmacologic intervention for patients does not help. Some authors have suggested that many of these patients have a flap of mucosa causing the obstruction that may be incised endoscopically with favorable results (Thurairaja and Studer, 2008). Others have not found this to be a common cause of retention (Simon et al., 2006).

A significant number of patients with orthotopic reservoirs will develop abdominal wall or incisional hernias postoperatively. In the series from Ulm, the estimated risk by Kaplan-Meier analysis was 4% at 5 years and 6% at 10 years (Hautmann et al., 2011). In a prospectively followed patient population, it was as high as 13% at 3 years (Fairey et al., 2013). These fascial defects may reduce the efficiency in completely evacuating the neobladder by reducing the ability to effectively increase intra-abdominal pressure.

In women, the exact cause of retention is still unclear. Some have suggested that posterior prolapse of the pouch may contribute to late retention, and posterior support by means of omental flaps and sacrocolpopexy has been advocated (Ali-El-Dein et al., 2002; Lee et al., 2004; Stein and Skinner, 2004; Stenzl and Höltl, 2003). Ali-El-Dein et al. (2002) elegantly studied the possible causes of chronic retention after radical cystectomy and orthotopic bladder substitution in women. In a series of 136 women undergoing radical cystectomy and orthotopic substitution, 16% were found to be in chronic retention. Video-urodynamics showed that retention appeared to be mechanical in nature; the pouch has fallen back in the wide pelvic cavity, resulting in acute angulation of the posterior pouch–urethral junction. In addition, herniation of the pouch wall through the prolapsed vaginal stump was observed in most patients. Pelvic floor electromyography demonstrated complete pelvic floor silence during voiding, suggesting that urinary retention was not related to a neurogenic cause. The authors suggested that transposition of the omentum behind the reservoir, suturing of the peritoneum on the rectal wall to the vaginal stump, suspension of the vaginal stump by the preserved round ligaments, and suspension of the pouch near the dome to the back of the rectus muscle at cystectomy would help reduce the incidence of chronic retention. We have routinely performed a formal sacrocolpopexy suspension of the vaginal apex to the sacrum, but this alone has not eliminated retention (Bartsch et al., 2014).

Preservation of the uterus and its ligament support structures may significantly reduce the risk for retention in women and should be considered when feasible (Ali-El-Dein et al., 2013; Anderson et al., 2012). Others have suggested that preservation of the neurovascular bundle that runs along the lateral vaginal wall is important in allowing effective relaxation of the urethral sphincter to empty (Gross et al., 2015). None of these theories has yet been addressed with a prospective randomized trial.

Key Points: Continence and Urinary Retention

- Daytime continence develops gradually over 3 to 6 months in most patients and is ultimately achieved in 80% to 90% of both male and female patients.

- Persistent nocturnal incontinence is common, observed in 20% to 50% of patients. Nocturnal continence may continue to improve beyond 12 months from surgery and may improve with timed voiding.
- Factors influencing continence rates include age, intestinal segment used, and application of a prostate-sparing technique.
- Failure to empty or urinary retention has been reported in 4% to 10% of men and 20% to 60% of women.

Follow-Up for Patients With Orthotopic Diversion

There is no consensus on the ideal follow-up regimen for patients with orthotopic diversion. Imaging techniques include intravenous urography (rarely performed today), CT urography, magnetic resonance imaging, and ultrasonography. Physicians in the United States tend to depend more on radiographic imaging, whereas those in Europe often rely more on ultrasound evaluation. Regardless of the type of imaging, the follow-up regimen can be divided into three time segments:

- Early evaluation (first 4 months) to identify early ureteroileal anastomotic strictures caused by technical difficulties or poorly vascularized distal ureters
- Intermediate period (4 months to 3 years) primarily focused on detecting cancer recurrence. This is best managed with CT or other cross-sectional imaging, which also allows evaluation of the upper tracts and reservoir for stones or obstruction. The frequency of the follow-up can be risk-adapted according to the pathologic findings at the time of cystectomy and the risk for subsequent recurrence.
- Long-term follow-up (beyond 3 years) to detect pouch stones, late upper tract obstruction, and urothelial carcinoma arising in the urethra or upper tracts

Our current follow-up scheme is shown in Box 141.1, but others have been described (Thurairaja and Studer, 2008; Yafi et al., 2012). We routinely perform cytology on both voided urine and in selected cases urethral wash in male patients with orthotopic diversion, especially those with CIS in their prostatic urethral pathology. It does require a cytologist with experience in looking at urine specimens from neobladder patients to be adept at evaluating them. Women should be evaluated with bimanual examination and voided cytology, because urethral recurrence, although rare, will not be evident on CT scan. Cystoscopy should be performed in any patient who develops new-onset retention, a change in voiding pattern, or hematuria.

Box 141.1

Suggested Follow-Up Protocol for Bladder Cancer Patients After Cystectomy and Orthotopic Diversion

Every 4 Months First Year, Then Every 6 Months to 3 Years, and Then Annually

Physical examination including pelvic and rectal examination
Serum comprehensive metabolic panel, complete blood count

Annual Visits Only

Urethral wash cytology (if carcinoma in situ on pathology)
Vitamin B_{12} level
Prostate-specific antigen (if prostate cancer on pathology)

Imaging Depending on Cystectomy Pathology

Stage pT3 or N+ or higher: computed tomography (CT) of abdomen and pelvis with intravenous contrast, CT of chest, or chest radiograph at each visit
Stage pT2 or lower: CT abdomen and pelvis with IV contrast and chest radiograph at 4 and 12 months, then annually to 5 years, and then every 2 years thereafter (may replace with ultrasonography after 3 years)

Key Points: Complications From Orthotopic Neobladders and Recommended Follow-Up

- Early morbidity and mortality of cystectomy and orthotopic diversion are not increased compared with ileal conduit.
- Undrained urine leak is best managed using percutaneous drains and bilateral nephrostomy tubes when necessary. Early open surgical revision should be avoided.
- The majority of late urologic complications related to the neobladder can be managed using endoscopic techniques.
- Patients require regular follow-up imaging to identify upper tract obstruction and stones, which may be clinically silent.
- Follow-up should include physical and pelvic examination and urethral cytology to identify urethral recurrence, which occurs in approximately 10% of males and rarely in females.

Quality of Life After Orthotopic Urinary Diversion

During the past several decades, there has been an increasing focus on quality-of-life issues and outcomes in various urologic diseases. This has been aided by the development of new health-related quality-of-life (HRQoL) instruments for use specifically in urology. Urinary diversion is often a life-altering procedure, and quality-of-life issues are becoming increasingly important in selection of the type of urinary diversion. Urinary incontinence and leakage are the most commonly investigated domain among HRQoL in bladder cancer patients.

Initial studies in the 1980s pioneered comparative evaluation regarding quality-of-life issues in patients with different forms of urinary diversion after cystectomy (Månsson et al., 1988). They demonstrated that, in general, patients were satisfied with their diversion and adapted reasonably well socially, physically, and psychologically. This group also demonstrated the importance of how quality-of-life data are collected in terms of the results obtained (Månsson et al., 2004).

A study by Henningsohn et al. showed similar distress levels between orthotopic neobladder patients and matched control populations 1 year after surgery; however, another study showed that nearly one-half of cystectomy patients report general distress (Henningsohn et al., 2002; Palapattu et al., 2004). Most studies point out the importance of body image in patients undergoing urinary diversion.

Hart et al. (1999) reported on a total of 221 patients (25 ileal conduit, 93 cutaneous Kock pouch, and 103 orthotopic neobladder) who completed four self-reported questionnaires including a profile of mood states and adapted versions of the sexual history form, body image dissatisfaction scale, and quality-of-life questionnaire. This study compared self-reports of emotional distress; global quality of life; sexuality; body image dissatisfaction; urinary diversion problems; and problems with social, physical, and functional activities. Regardless of the form of urinary diversion, the majority of patients reported good overall quality of life, little emotional distress, and few problems with social, physical, or functional activities. **After controlling for age, the researchers found no significant differences in any quality-of-life area among the urinary diversion subgroups.** Several studies suggest that patients with a neobladder report better body image compared with patients who have an ileal conduit (Table 141.3). This may reflect not only differences in individuals' perceptions of their body but also cultural values and norms (Shim et al., 2014).

TABLE 141.3

Summary of Comparative Urinary Diversion Health-Related Quality-of-Life Studies Since 2000

REFERENCE	INSTRUMENT	NO. OF PATIENTS	YEAR	POPULATION	FINDINGS
McGuire et al.	SF-36	76	2000	United States	Lower mental QoL scores in IC patients compared with population norm
Fujisawa et al.	SF-36	56	2000	Japan	No differences detected between groups
Hobish et al.	EORTC-QLQ-C30	102	2000	Austria	**Higher QoL scores in NB**

					patients
Hara et al.	SF-36 + informal questionnaire	85	2002	Japan	No differences detected in general HRQoL
Dutta et al.	SF-36 + FACT-G	100	2002	United States	**Marginally higher HRQoL scores detected in NB group**
Protogerou et al.	EORTC-QOL-C30, informal questionnaire	108	2004	Greece	Urinary and sexual function impairments present after cystectomy but no HRQoL differences between groups
Kikuchi et al.	FACT-BL	35	2006	Japan	**Lower body image scores among ileal conduit patients**
Gilbert et al.	BCI	315	2007	United States	Decreased urinary HRQoL among NB group
Saika et al.	EORTC-QLQ-C30	78	2007	Japan	No significant difference between IC and NB
Autorino et al.	SF-36	79	2009	Italy	No difference between IC and NB but physical, emotional,

					and social QoL scores below population norm
Sogni et al.	EORTC-QLQ-C30 + EORTC-QLQ-BLM30	34	2008	Italy	**Global health status higher in NB group but not significant**
Philip et al.	SF-36 + informal questionnaire	52	2009	England	**NB group had significantly better physical functioning**
Somani et al.	EORTC-QLQ-C30 + SWLS	32	2009	England	No HRQoL difference before or after cystectomy
Hedgepeth et al.	BCI	224	2010	United States	No difference between IC and NB groups
Erber et al.	EORTC-QLQ-C30 + EORTC-QLQ-BLM30	58	2012	Germany	**Higher HRQoL scores among NB vs. IC patients**

HRQoL, Health-related quality of life. *IC,* intermittent catheterization to empty neobladder; *NB,* ileal neobladder.

Most of the studies that have evaluated and compared quality-of-life issues in patients undergoing various forms of urinary diversion have been criticized for methodologic problems that limit their conclusions (Gerharz, 2007; Gerharz et al., 2005; Porter et al., 2005)**. Critical analyses of the current quality-of-life literature suggest that there is not enough evidence to conclude that there is a clear quality-of-life advantage for patients undergoing continent diversion** (see Table 141.3). Porter and Penson (2005) performed a systematic review to determine if any differences exist in HRQoL outcomes among different types of urinary diversion after radical cystectomy. Of 378 initial articles, only 15 studies met all of their inclusion criteria. None of the studies were randomized trials, and only one was prospective. **Common limitations included unvalidated HRQoL outcome instruments, use of general HRQoL outcome instruments only, lack of baseline data, cross-sectional analysis, and retrospective study design.** The authors found that the current body of published literature is insufficient for it to be concluded that any form of urinary diversion is superior to another on the basis of HRQoL outcomes. Gerharz came to similar conclusions (Gerharz, 2007; Gerharz et al., 2005).

There have been a number of efforts to develop a new tool that is more specific to patients with muscle-invasive bladder cancer. These include general—or generic—instruments, such as the Medical Outcomes Study Short Forms (SF-36 and SF-12) and EuroQol five-dimension questionnaire (EQ-5D). There are other condition-specific instruments that assess issues associated with urinary diversion, including the Functional Assessment of Cancer Therapy Bladder Cancer subscale (FACT-BL) and the European Organisation for Research and Treatment of Cancer Quality of Life Bladder Module (EORTC QLQ-BLM30) (Gilbert et al. 2007; Leone et al. 2017). These tools have been limited when used for comparing continent versus conduit diversion because of variation in weighting of specific symptoms that only occur with one diversion type (Gellhaus et al., 2017). A 23-item neobladder HRQoL instrument called the IONB-PRO was recently developed to provide more specific information pertaining to issues that arise for patients with neobladders (Siracusano et al., 2014). Each has its advantages and disadvantages, especially when applied to a specific group of patients.

The more recent studies using these condition-specific validated assessment tools are still all cross-sectional and retrospective, and there is still room for methodologic improvements. A recent systematic review favored ileal neobladder in terms of higher quality-of-life scores (Ghosh et al., 2016). Another large meta-analysis of observational HRQoL studies using validated questionnaires identified significantly better quality-of-life outcomes among patients treated with orthotopic neobladders in a subanalysis of studies based on the EORTC QLQ-C30 (Cerruto et al. 2016). Future studies in this area must incorporate prospective data collection, provide longer-term follow-up, and incorporate validated disease-specific HRQoL outcome instruments. With all instruments, the functional outcomes of different diversions and quality of life remain very difficult to assess, and it is extremely difficult to develop a single instrument that allows detailed comparison among different types of diversions.

In summary, there are no clear data showing an overall quality-of-life advantage for patients undergoing neobladder reconstruction, and most patients will clearly adapt to whatever specific challenges their urinary diversion presents to them. Several prospective studies that focus on longitudinal health-related quality-of-life assessment among cystectomy and urinary diversion patients as primary outcomes are currently ongoing. As the results of these studies become available, our understanding of the factors that contribute to and drive health-related quality of life in this patient population should improve. Nevertheless, when presented with the option, most patients will choose orthotopic diversion simply because it seems the most natural and avoids a permanent stoma, and having this option may encourage patients to more readily undergo definitive treatment of their bladder cancer. Patients must, however, have realistic expectations about the risk for incontinence and the possible need for self-catheterization.

Key Points: Quality of Life After Urinary Diversion

- Most quality-of-life studies that have evaluated and compared patients undergoing various forms of urinary diversion have been criticized for methodologic problems that limit their conclusions.
- The current body of published literature is insufficient to conclude that any form of urinary diversion is superior to another on the basis of health-related quality-of-life outcomes, though most studies report better body image with neobladders.

Minimally Invasive Urinary Diversion

Khurshid A. Guru MD

The frequency of implementing a minimally invasive approach to cystectomy has increased from 26% in 2010 to 39% in 2013 (Bachman et al., 2017). Robot-assisted surgical approach for pelvic urologic oncology has been in practice for more than a decade (Guru et al., 2008; Menon et al., 2003), and the technique for robot-assisted radical cystectomy (RARC) with lymph node dissection has been established (Poch et al., 2013). Oncologic outcomes after RARC and lymph node dissection have proven to be safe and efficacious in early and long-term follow-up (Ahmed et al., 2014; Hellenthal et al., 2011; Raza and Guru, 2015; Parekh et al., 2018). The Roswell Park Comprehensive Cancer Center group has advocated the Quality Cystectomy Score based on star-based criteria to offer quality care to patients undergoing RARC (Hussein et al., 2017c). These quality criteria range from neoadjuvant chemotherapy consultation to adequate lymph node yield and 30-day mortality. **Patients who underwent a minimally invasive approach to cystectomy were more likely to receive neoadjuvant chemotherapy based on the National Cancer Database (NCDB) analysis** (Bachman et al., 2017). Despite validation of oncologic equivalency of RARC based on several randomized controlled trials (Bochner et al., 2015; Khan et al., 2016; Nix et al., 2010; Parekh et al., 2018), the role of intracorporeal urinary diversion (ICUD) has not been investigated.

Laparoscopic approach to urinary diversion has evolved since 1992, and its adoption was hindered by prolonged operative times, limitations of instrument maneuverability used with conventional laparoscopy, and a steep learning curve (Kozminski and Partamian, 1992; Potter et al., 2000; Sanchez de Badajoz et al., 1992). These difficulties led to hybrid procedures, in which extirpation and lymph node dissection were performed by conventional laparoscopy, and diversion was completed using a modified open approach (Haber et al., 2007).

Several perceived advantages of robot-assisted approaches for bladder cancer include less pain, minimal blood loss, and earlier return of bowel function, which ultimately help in quicker return to previous quality of life (Challacombe et al., 2011).

Incorporation of Robot-Assisted Approach

Data from the NCDB during the early learning curve of RARC and incorporation of ICUD (2010–2013) has shown slower adoption of minimally invasive approaches by academic institutions (Bachman et al., 2017). This possibly was related to multiple factors, such as the presence and availability of the surgical robot for cystectomy (longer operative time versus its use for kidney or prostate) and a larger proportion of surgeons with limited training and experience in minimally invasive approach. Based on the NCDB for radical cystectomy, a median hospital volume of 12 cases per year with an average volume of only 2 procedures has been reported (Waingankar et al., 2017). **Despite the slow adoption and early incorporation of this approach, rate of conversion to open was only 4.3% in more than 3000 procedures** (Bachman et al., 2017). This can be interpreted in multiple ways; early adoption of robot-assisted radical prostatectomy could have paved the way for RARC identifying ways to reduce the morbidity of radical cystectomy. The negative impact of this could be suboptimal oncologic procedures during the learning curve and performing urinary diversions that did not meet the standards set by open experts. Attempts to simplify operative steps used in well-established techniques of urinary diversion are believed to lead to a smaller radius pouch and ultimately a geometric low capacity and high-pressure reservoir (Hautmann, 2017).

More than 2750 RARCs have been registered in the International Robotic Cystectomy Consortium (IRCC) database, a quality assurance conglomerate of 50 surgeons at 37 institutions in 13 countries. Based on previous data published in 2013 from the IRCC, only 18% of procedures have been performed with a complete intracorporeal approach (Ahmed et al., 2014). Recent updates from the IRCC in 2018 show that **incorporation of ICUD for the robotic cystectomy–focused group has increased from 9% in 2005 to 97% in 2016 with an annual increase of 11%. This dramatic increase was primarily demonstrated for ileal conduit** (Hussein et al., 2018). This trend has shown an earlier start in Europe than North America. Whether a robot-assisted approach to radical cystectomy encourages surgeons more toward performing ileal conduit diversions, thereby limiting continent urinary diversions, remains unclear. A single-institution study from a high-volume RARC center has shown that surgeon preference may have led to choice of incontinent urinary diversion in only 8% of patients eligible to continent urinary diversion (Hussein et al., 2016a).

Key Points

- Advantages of robot-assisted approach for bladder cancer include less pain, minimal blood loss, and earlier return of bowel function.
- Incorporation of intracorporeal urinary diversion has recently increased (annual increase of 11%).
- Ileal conduit is the most commonly performed diversion with the robot-assisted approach.

Patient Selection

The selection criteria (including high body mass index, locally advanced disease, older age, prior abdominal surgery) have significantly broadened as the learning curve has flattened (Wilson et al., 2015). One of the contraindications for the minimally invasive approach is decreased cardiac and pulmonary compliance because of the inability to tolerate the steep Trendelenburg position, especially with prolonged operative duration during ICUD. This has been addressed with newer technology available in the Xi model of the da Vinci Surgical System and use of the AirSeal, which has allowed surgeons to operate in a less-steep Trendelenburg position. Use of ileum is contraindicated in patients with short bowel, severe inflammatory bowel disease, and postradiation enteritis. Absolute and relative contraindications for neobladder are similar to open surgery. The absolute contraindications include involvement of the urethra distal to the prostate and inadequate renal (serum creatinine >2 mg/dL) and poor hepatic functions (Parekh and Donat, 2007).

Surgeon Choice

The best practices recommended by the Pasadena Consensus Panel (Wilson et al., 2015) **advise surgeons to focus on oncologic outcomes early on in their initial experience.** A stepwise incorporation of intracorporeal ileal conduit (building an experience of more than 30 to 100 procedures) and ultimately incorporating continent urinary diversion to their practice (25% to 50%) is recommended. Once the learning curve has flattened, the **consensus considers adequate overall operation of 4 hours or less (if ileal conduit is performed) and less than 5 hours with neobladders** (Wilson et al., 2015).

Preoperative Care

Enhanced Recovery After Surgery

Multimodal perioperative pathways, especially enhanced recovery after surgery (ERAS), has evolved with more than 20 key components and has been tailored by several cystectomy experts (Collins et al., 2016). Recent modifications include early use of alvimopan, intraoperative goal-oriented fluid optimization, immediate initiation of oral diet, and reduced narcotic use (Wilson et al., 2015). Xu et al. (2015) compared traditional pathway with an enhanced recovery protocol and reported decreased opioid usage per day, incidence of ileus, and hospital stay; however, they reported more pain. **Opioid use for breakthrough pain underwent a radical change from opioid patient-controlled analgesia (PCA) and epidurals to high-dose acetaminophen and/or ketorolac.**

Patients who underwent RARC with ICUD and participated in the ERAS pathway had shorter length of stay and were more likely to receive a neobladder. The ERAS group was associated with significantly lower overall gastrointestinal-related complications and readmission rates at 90 days. Participating in the ERAS pathway and younger age were independently associated with a hospital stay of less than 10 days (Miller et al., 2017; Tan et al., 2017). Pooled meta-analysis of 13 studies with 1493 patients showed that implementation of ERAS protocols after surgery reduced complications and length of stay without affecting overall readmission rates. They concluded that **emphasis on the development of integrated multidisciplinary clinical pathways can improve outcomes and increase patient satisfaction** (Tyson and Chang, 2016). Despite the focus on reducing the length of stay, it is important to understand its impact on patients. In a consecutive study of 484 patients, the team at University of Michigan found that reduced length of stay (less than 5 days) carried a (twofold) increased risk of 90-day major complications (Osawa et al., 2017). **Additional emphasis should be given to care for patients after discharge, especially in areas such as trained nurse visit and home health issues such as hydration, exercise, and ambulation.**

Solids and clear fluids are allowed until 6 and 2 hours, respectively, before induction of anesthesia (Smith et al., 2011). **Mechanical bowel preparation and oral antibiotics preoperatively are no longer recommended.** Bowel preparation can lead to electrolyte imbalance, especially in elderly patients, and may lead to spillage of liquid content during intracorporeal opening of bowel. Several studies have shown no clear benefit of oral mechanical bowel preparation before surgery (Cerantola et al., 2013).

Intermittent pneumatic compression and leg stockings are recommended. **To avoid significant thromboembolic complications, anticoagulant treatment is recommended with low-molecular-weight heparin based on the body weight before and up to 4 weeks after surgery** (Johar et al., 2013; Sun et al., 2015)**. Broad-spectrum intravenous antibiotics are preferably given up at induction and maintained as needed.**

Key Points

- Mechanical bowel preparation *and* oral antibiotics should be avoided.
- Anticoagulant treatment can help avoid significant thromboembolic complications.
- Preoperative broad-spectrum intravenous antibiotics are preferably given up to 1 hour.
- Enrollment in the ERAS pathway helps with reduction in length of stay, complications, and readmissions.

Patient Position and Port Placement

After induction of general endotracheal anesthesia, a nasogastric tube and a Foley urinary catheter are inserted. The patient is placed in lithotomy position with arms adducted and padded. The legs are also abducted and slightly lowered on spreader bars or stirrups. Traditionally the patient has been positioned in steep Trendelenburg position; meanwhile with the da Vinci Xi Surgical System, which integrates table motion with the ability to maneuver the patient position without undocking the robot, has also explored the ability to perform the procedure in lesser steep or even in a flat position. The abdomen is safely insufflated with Veress needle or Hassan technique depending upon the experience and the need (e.g., previous abdominal surgery). A six- to seven-port transperitoneal approach is used and all the ports after the camera port are placed under direct vision in a more cephalad orientation (Fig. 142.1). This **cephalad positioning of the ports helps in small bowel maneuvering during urinary diversion and extended lymph node dissection along the aortic bifurcation.** In the six- to seven-port configuration, the 12-mm camera port (8 mm for the da-Vinci Xi Surgical System) is placed above the umbilicus (midline or slightly to the left of midline). Two robotic ports (8-mm arms) are placed symmetrically at the level of the umbilicus on the left and right side, lateral to the rectus sheath. While performing the neobladder, some expert surgeons use an additional left side port (12–15 mm) above the left 8-mm robotic arm port, and this port is placed just above and medial to this port. The robotic arm just above and medial to the anterior superior iliac spine could be used alternatively (hybrid) with an assistant instrument or by inserting an additional robotic arm inside the 15-mm laparoscopic port for stapling during neobladder creation. A 5-mm (12-mm for neobladder) port is placed between the camera and the right robotic arm port. An extra-short 12-mm port can be inserted in the suprapubic area for bowel re-anastomosis while performing the “marionette” ileal conduit and the “W-neobladder” as performed by the author. This port helps in aligning the bowel during re-anastomosis and can be extended and converted to a Pfannesteil incision for specimen removal.

FIG. 142.1 Overview of common theme and variation in port placement for intracorporeal urinary diversion.

With use of a stepwise approach, "the technique of spaces" is important in completing extirpation of the bladder and lymph nodes. Dividing the procedure into well-defined steps facilitates teaching and keeps the procedure focused. The four spaces of dissection in men are periureteral, lateral pelvic, anterior rectal, and retropubic spaces (Poch et al., 2013). Extended lymph node dissection is performed up to the aortic bifurcation, which helps with the crossing of the left ureter to the right side for the urinary diversion. Once the bladder and the lymph nodes are placed in the specimen bags, attention is directed toward ICUD. **The entire procedure can be performed with a 0-degree lens.** Occasionally, it is advantageous to use a 30-degree down lens for a deep female pelvis during an extended lymph node and vascular pedicle dissection.

Key Points

- A six- to seven-port transperitoneal approach in a more cephalad position helps in maneuvering small bowel.

- The robotic arm could be used alternatively with an assistant instrument by inserting an additional robotic arm inside 15-mm laparoscopic port.
- A 0-degree lens can be used for the entire procedure.
- Robotic arms can be undocked, and steep Trendelenburg position is reduced for ease of urethra-neobladder anastomosis.

Anatomic Considerations in Men

The radical approach to cystectomy has been modified and nerve sparing is more likely feasible because of the numerous anatomic studies that have focused on nerve preservation and easier operative opportunity because of the 3D view, magnification, and ability to maneuver in a small narrow space with help of a surgical robot (Fig. 142.2). This approach should be used only in patients who have an anatomically safe location of tumor, lower tumor burden, and adequate baseline sexual function, making such patients more amenable to nerve-sparing not only for sexual preservation but also for continence after creation of a neobladder.

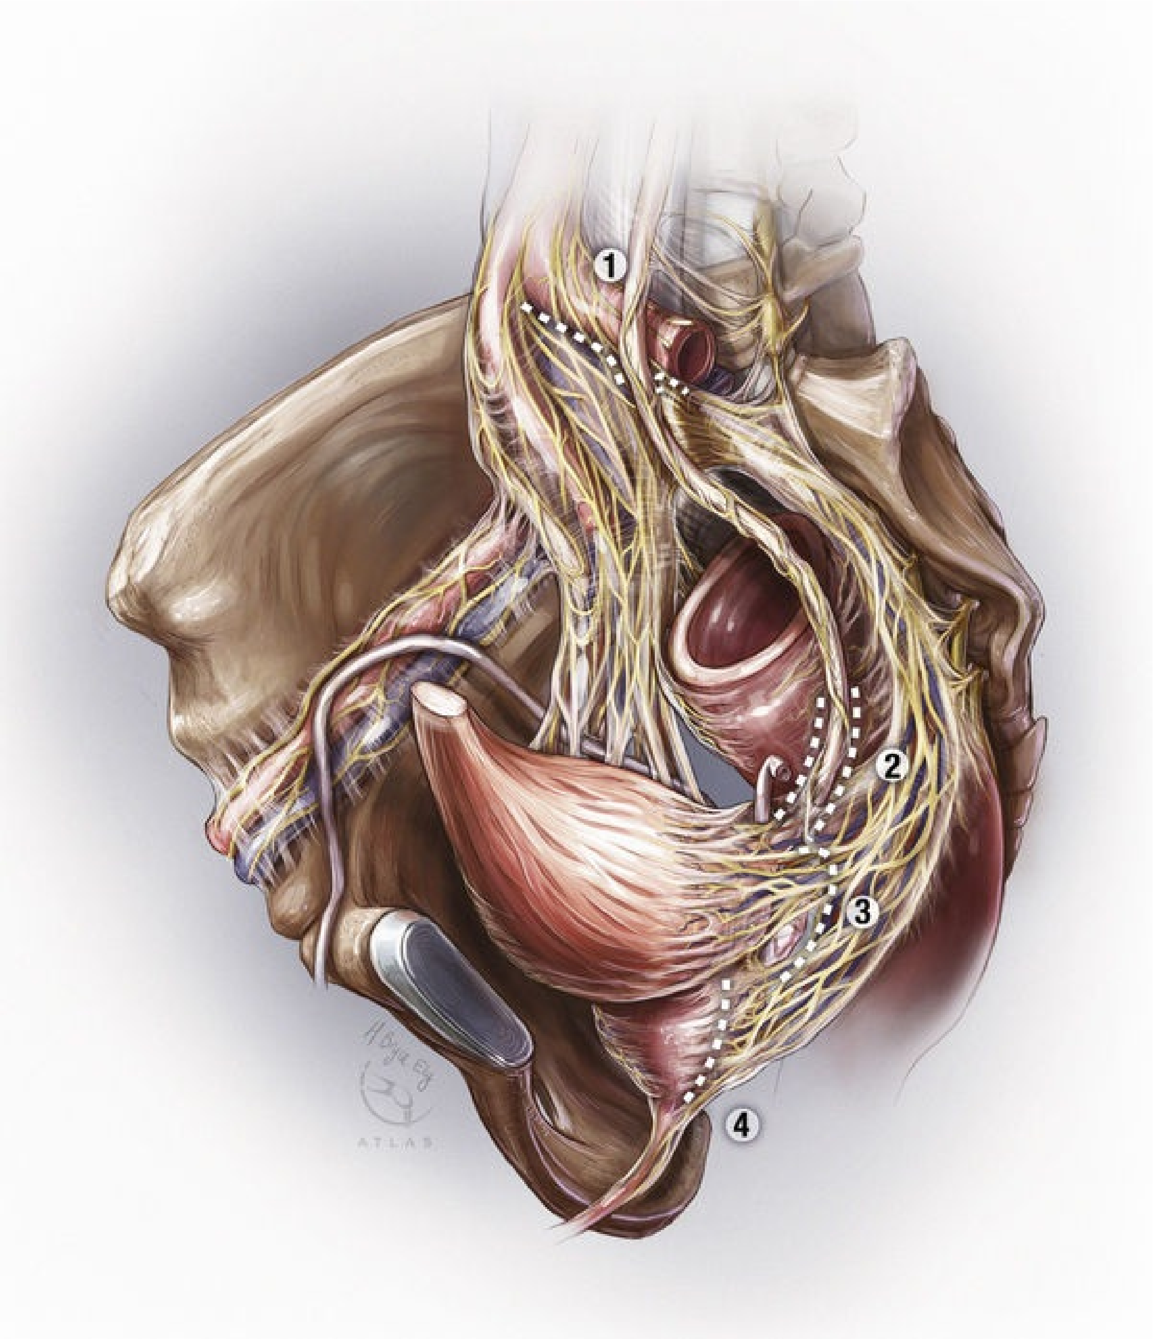

FIG. 142.2 Critical areas of possible nerve damage during nerve-sparing radical cystoprostatectomy in men.

The nerves are at risk at their origin in the medial aspect of the common iliac vessels and the presacral area (1). It is critical to keep in mind the course of the pelvic plexus while performing an extended lymph node dissection because it can risk sexual function and continence (Walz et al., 2016). **The approach to nerve sparing has to also start early on from the high ligation**

of the bladder vascular pedicle (ensuring preservation of the proximal neurovascular complex) to the incision of the peritoneum in the pouch of Douglas overlying the rectovesical space (2). Once the ampullae of the vasa are identified and safely dissected, an athermal approach of the seminal vesicles, while sparing the Denonvillier fascia (where the pelvic plexus is mostly concentrated), should be attempted (Schwalenberg et al., 2010). It is safe to avoid manipulation and sometimes spare the middle to lower part of the seminal vesicles (3). The proximal prostatic pedicles should be controlled close to the prostate, and attempts to perform an intrafascial, traction-free, and athermal nerve preservation should be made. The complete lateral nerve preservation (i.e., Veil of Aphrodite) and its distal extent (4) are difficult to complete without dissecting the apex of the prostate after dropping of the bladder. **Computer-assisted dissection that involved 3D reconstruction of the inferior hypogastric plexus has demonstrated the precise location and distribution of pelvic nerves helping in continence and erectile function** (Alsaid et al., 2009; Takenaka et al., 2005).

Approximately one-third of the cross-sectional external urethral sphincter area has shown to be laterally overlapped by the dorsal venous complex at the prostatic apex (Ganzer et al., 2014). Doppler studies have **shown dorso-cavernous anastomoses play an important role in the cavernous arterial hemodynamics** (Erdogru et al., 2001). Vascular anastomoses have also been found between different arterial supplies (dorsal, the cavernous, and the bulbourethral) of the penis. These arteries, except for bulbo-urethral arteries, have been shown to have function of contractibility based on their muscular walls and accompanying nerves (Diallo et al., 2013). At the site of the external urethral sphincter, cavernosa nerves converge close to the urethra before they penetrate the muscular pelvic floor (Diallo et al., 2013). Anatomic study of 18 adult male cadavers has shown that the external urethral sphincter receives part of innervation through special branches originating from the dorsal nerve of penis after it splits from the pudendal nerve. This study elegantly shows that these branches located as close as 3 mm from the prostatic apex, and 50% had shown only unilateral innervation, emphasizing the need for a meticulous periurethral dissection (Narayan et al., 1995).

Anatomic Considerations in Women

The pelvic splanchnic nerves contain adrenergic and cholinergic fibers and are also responsible for vaginal lubrication and genital swelling during sexual arousal (Trimbos et al., 2001). Therefore damage to these nerves causes decreased flow to the vagina and vulva (Moszkowicz et al., 2011). The inferior hypogastric plexus arises from the hypogastric and pelvic splanchnic nerves and is retroperitoneal in location. It radiates anterolateral to the rectum, passing laterally to the cervix and the vaginal fornix and **extending to the lateral vaginal wall and the base of the bladder, where it is most vulnerable to injury** (Moszkowicz et al., 2011). The cavernous nerves originate along the **lateral edge of the vagina and travel within the vesico-vaginal septum** to pass through the urogenital diaphragm (Baader and Herrmann, 2003).

Advances in studies regarding dissection of the female **urethra have shown that despite removal of bladder neck and cranial third of urethra, urinary continence can still be preserved**. Manipulation of the urethral Foley balloon helps in better defining the bladder neck and the key surrounding landmarks for preservation. Proper posterior dissection and excellent magnified visualization allow for ease in preservation of the periurethral complex and the endopelvic fascia. The majority of striated intrinsic sphincter is situated in the mid- to distal third of the urethra and can be preserved while adhering to safe oncologic practices. In females the nerve branches supplying the urethra course close to the lateral vaginal wall and require preservation of the tissue around the proximal urethra and lateral to the bladder neck (Stenzl et al., 1995). Despite the controversy, the **innervation should be preserved for maintenance of continence. It is preferred that the anterior vaginal wall is preserved in patients with goals of nerve sparing.** I avoid removal of the specimen via the vagina to prevent trauma to the preserved complex and prefer a small Pfannesteil incision in these select situations.

Ileal Conduit

Transfer of Left Ureter and Selection of Bowel

The **left ureter is crossed below the sigmoid mesentery and over the great vessels to the right side.** It is important to identify patients with duplication of the ureter so that they can be implanted separately or together depending upon the caliber of the ureters. If the left ureter is short, the sigmoid colon is retracted with the fourth arm. Occasionally a 30-degree down lens helps to identify and free the proximal left ureter. A 12-cm–long segment of ileum is identified (15–20 cm proximal to the ileocecal valve). **Adequate bowel length on the ileocecal end of the bowel should be left in place to avoid metabolic disturbances and kinking once the conduit is exteriorized and repositioned.** It is also critical to avoid use of redundant segment of ileum to prevent residual urine and subsequent stasis of urine, infections, absorptive and metabolic complications, and subsequent loss of renal function.

Marionette Stitch

A 60-inch 1-0 silk suture using a Keith needle is introduced via the hypogastrium of the anterior abdominal wall and is passed through the distal end of the bowel segment (future stoma) and brought back through the same location on the anterior abdominal wall. The marionette stitch (Fig. 142.3) is held together using a surgical instrument; the **benefit of not tying the marionette stitch is to allow free movement of the bowel segment during the creation of the conduit.** The marionette stitch manipulates the bowel segment to adjust for the limitation of fixed ports and enables mobilization of different areas of the conduit into the surgical field. It is helpful especially in patients with limited distance between physical boundaries of the abdomen/pelvis and the actual operative space. It can be placed farther down in the pelvis to keep the operative field in range of optimal mechanical joint movements of the robotic instruments.

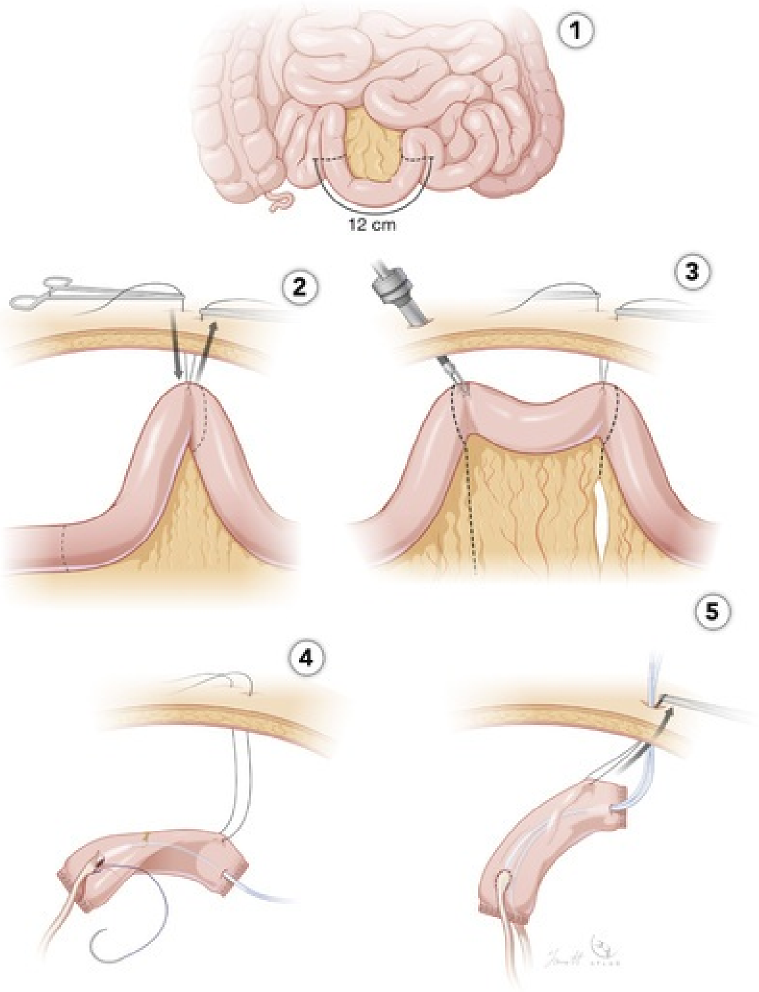

FIG. 142.3 Illustrated schema of key steps in creating the ileal conduit using “marionette” technique. *1,* A 12- to 15-cm ileal segment is harvested approximately 15 cm away from the ileocecal valve. *2,* A 60-inch 1-0 silk suture using a Keith needle is passed through the distal end of the bowel segment and brought back through the same location on the anterior abdominal wall. The marionette stitch is held together using a surgical instrument. *3,* The fourth arm is used to hold the proximal segment of the bowel at stretch opposite to the stoma end held by the marionette stitch. The mesentery is then incised to create 2 mesenteric windows. *4,* Once the marionette is lowered, the ureters are implanted with minimal traction to the proximal end of the ileal conduit. The stent is secured to the conduit by a using 3-0 chromic stitches to prevent accidental dislodgment of the stent. Ureters are anastomosed and the bowel is restored. *5,* The stoma is created.

Isolation of the Bowel Segment and Creation of the Ileal Conduit

The fourth arm is used to hold the proximal segment of the bowel at stretch opposite to the stoma end held by the marionette stitch; meanwhile the hook cautery is used to incise the peritoneum of the bowel mesentery. It is important to keep the appropriate orientation of the bowel and avoid narrowing of the base of the conduit limits (limit mesenteric blood supply). Another alternative is to use a vascular stapler across the mesentery, which makes this process quicker. After the two mesenteric windows are created, a 45-mm Endo GIA stapler is used to divide the bowel proximally and distally. The incised ends are held together using a 0-silk suture to avoid malrotation during anastomosis. The bowel re-anastomosis is not established at this point. **Ileal conduit segment washout has been abandoned because it does not reduce risk of infection and also to avoid spillage during stent manipulation and ureteroileal anastomosis.**

Ureteroileal Anastomosis

The two commonly employed techniques of anastomosis are the Bricker and Wallace. A Bricker anastomosis is a refluxing end-to-side anastomosis and is easy to perform while keeping the two renal units separate. Meanwhile the Wallace technique joins the ends of the two ureters in a Y format, anastomosing a single limb to the proximal portion of the ileal conduit (Rehman et al., 2011).

Two openings are created on either side of the proximal end of the conduit. To avoid risk of strictures, **I avoid the use of electrocautery; instead, I use a cold scissors to create a wide buttonhole enterotomy by removing the serosa in the proximal end of the ileum.** Once the marionette is lowered, the ureter is implanted with minimal traction and stretching of the proximal end of the ileal conduit. Once efflux of clear urine is seen, wide spatulation is carried out, and the fourth arm is used to retract the cut end of the distal ureter**.** I prefer to implant the left ureter first for ease of anastomosis.

A few critical issues should be kept in mind while performing this anastomosis. The key is to place the initial suture in the conduit opening first (outside in) and then into the angle of the incision in the ureter (inside out). The suture on the conduit side should be perpendicular to the proximal staple line of the conduit. This helps to align the ureter and avoids malrotation and back walling of the ureter. This initial suture sets the stage for a proper alignment and placement of the subsequent sutures. It is critical to understand that the position in which the anastomosis is carried out is not the final position in which the proximal end of the conduit will lay. Interrupted sutures can also be run along both sides halfway up to middle of the anastomosis after which the stent is placed. A Van-Velthoven-type, double armed, 4-0 Vicryl sutures approximately 5 cm long can also be used to suture the angle of the spatulation and continued along both sides. After completion of anastomosis of the posterior wall, the ureteral stent is introduced. A metal laparoscopic suction tube is passed into the distal conduit through the 15-mm right assistant port. The metal laparoscopic suction tube is pushed gently across the conduit and positioned at the junction of the conduit and the ureteral anastomosis. **The metal suction tip is held in place by the robotic needle driver to allow passage of stent through it without damaging the anastomosis. This maneuver helps to facilitate threading of the 90-cm, 8.5-Fr, and single-J ureteral stent with a guidewire into the renal pelvis. The guidewire is kept in the stent until it is secured to the conduit by using 3-0 chromic stitches to prevent accidental dislodgment of the stent.** The guidewire is removed only after the suture is placed because it is difficult to identify the stent because of lack of tactile feedback. The distal end of the ureter is excised completely and sent for final histopathology. The author does not routinely perform frozen section of the distal ureter. The ureteroileal anastomosis is then completed. Once the left side is anastomosed, the marionette is manipulated to turn the conduit on the other side, and the right ureteral anastomosis is performed in a similar fashion. The distal ends (external portion) of both ureteral stents are left draining through the 15-mm side port. The exterior portions of the stents should not be clamped to the drape to avoid accidental dislodgment during intracorporeal manipulation of the ileal conduit.

We also have started to preserve a flap of peritoneum while dissecting the right ureter (periureteral space) at the time of RARC and extended lymph node dissection. This peritoneal flap helps in covering the proximal ureteroileal anastomosis and retroperitonealize it to avoid an inflammatory response at the site of the anastomosis (Ahmed et al., 2017).

Restoration of the Bowel

We prefer to re-anastomose the bowel once the two ureters are anastomosed. This helps with ease of conduit manipulation and tailoring the bowel re-anastomosis to avoid kinking or tension. The feasibility of robot-sewn ileoileal anastomosis has been studied. A study of 48 consecutive patients was analyzed, and the operating time was only 23 minutes with no anastomosis leaks. The cost of anastomosis was significantly lower (<1%) in comparison with using staplers and may serve as an alternate approach (Loertzer et al., 2018).

Pre-Stoma Preparation

The robot is left docked and the instruments are removed. The surgeons scrub to create the stoma opening by making a cruciate incision in the anterior fascia and inserting the four stay sutures to anchor the conduit once it is externalized. After completion of four fascial sutures, the robotic arms are reinserted. The pelvis is examined for any bleeding and strings of all specimen bags are brought out via the suprapubic port. A vascular clamp is introduced via the stoma opening under direct vision into the abdominal cavity to grab the marionette stitch and the free ends of the ureteral stents. A Jackson-Pratt drain is introduced via the right assistant port, and the robot is de-docked once the robotic instruments have been removed. A Foley catheter is left as a pelvic drain. **Finally, the distal end of the conduit is brought out gently through the stoma site, ensuring proper orientation once the pneumo-peritoneum is lowered.**

Key Points

- The marionette stitch is not tied but held together using a surgical instrument to allow free movement of the bowel segment.
- Adequate length on the ileocecal end should be preserved to avoid metabolic disturbances and kinking once the conduit is exteriorized.
- We recommend avoiding using thermal approach in creating an enterotomy in ileum at the site of ureteral anastomosis and retroperitonealize the anastomosis.
- The guidewire is removed only after the anchoring suture is placed because it is difficult to identify the stent because of lack of tactile feedback.

Intracorporeal Neobladder

Since the last edition of this chapter, several techniques of intracorporeal neobladder have been developed, evaluated, and incorporated into clinical practice (Table 142.1). The port placement has been explained earlier and incorporates all modifications by various surgeons to accommodate to their techniques (see Fig. 142.1). Instead of describing each technique in detail, the key steps are presented in an easier illustrated format.

NR, Not reported.

Before embarking on an intracorporeal neobladder, the robotic arms are

de-docked from the ports, and the steep Trendelenburg position is reduced to 10 to 15 degrees to facilitate urethra-neobladder anastomosis. This may not be an issue with the da Vinci Xi Surgical System with its integrated operating room table. **The significant difference from the open approach is the performance of early neobladder-urethral anastomosis adopted by majority of institutions as advocated by the Karolinska group.** Several open configurations have been adopted and modified to be performed using a robotic interface.

Modified Studer Neobladder: The Karolinska Institute Technique

Configuration and Setup

The ileum is mobilized to ensure a tension-free anastomosis between the urethra and the future neck of the Neobladder. The orthotopic neobladder is tailored based on the Studer principles, and a U-shaped configuration is measured to ensure up to 25 cm from the ileocecal valve and up to 40 cm proximal to the neobladder-urethral anastomosis (Tyritzis et al., 2013; Fig. 142.4).

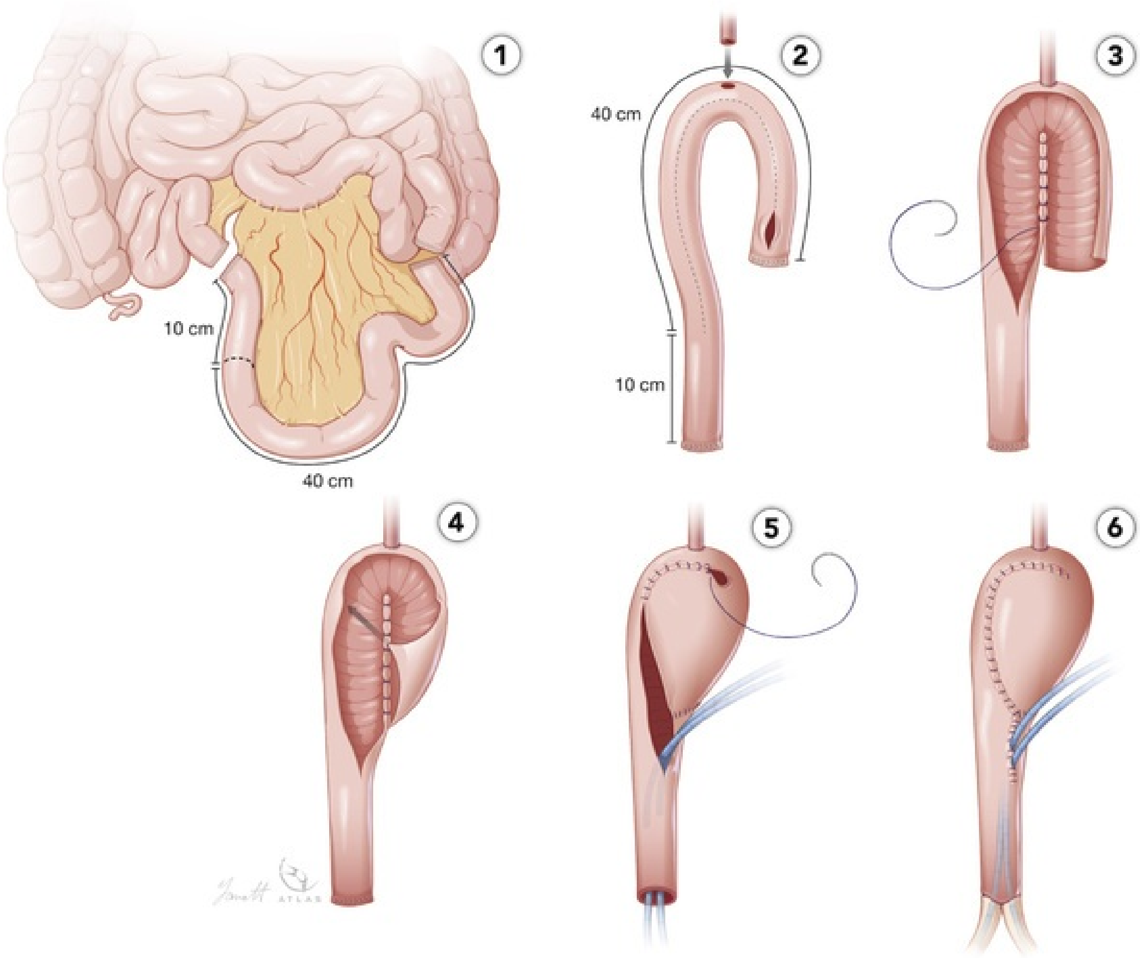

FIG. 142.4 Illustrated schema of key steps in creating the Karolinska modification of the Studer neobladder. *1,* A U-shaped configuration is measured to ensure up to 25 cm from the ileocecal valve and up to 40 cm proximal to the neobladder-urethral anastomosis. *2,* The neobladder-urethral anastomosis is performed by the Van-Velthoven technique with a 4-0 Quill suture. *3,* The posterior plate of the neobladder is closed using absorbable running sutures (2-0 or 3-0 V-Loc). The distal 40 cm of the isolated ileal segment is detubularized along the anti-mesenteric border. A 10-cm proximal isoperistaltic afferent limb is left intact to anastomose the ureters in an end-to-end fashion. *4 and 5,* After the posterior part is sutured, the distal half of the anterior part of the reservoir is also sutured in a similar fashion. *6,* Ureteroileal anastomosis is performed between the ureters and the isoperistaltic afferent limb. The stents can be externalized through the midline just above the pubic symphysis or internalized using double-J stents. The remaining part of the reservoir is then closed.

Neobladder-Urethral Anastomosis

The anastomosis is performed by the Van-Velthoven technique with a 4-0 Quill suture. Some anecdotal experiences have advocated not using the V-Loc suture because of the sharper and larger barbs that may traumatize the neobladder. **In situations in which it is difficult to approximate the bowel to the urethra easily, the neobladder is held in position between two customized Penrose drains rolled around the intestine (urethral end of the future neobladder)**.

Detubularization of Bowel

The distal 40 cm of the isolated ileal segment are detubularized along the antimesenteric border with cold scissors or **inserting a 24-Fr chest tube for ease of identification of most antimesenteric portion.** A 10-cm proximal isoperistaltic afferent limb is left intact to anastomose the ureters on the left side.

Creation of Neobladder

The posterior plate of the neobladder is closed using absorbable running sutures (2-0 or 3-0 V-Loc). After the posterior part is sutured, the distal half of the anterior part of the reservoir is also sutured in a similar fashion. **The anterior part of the reservoir is not sutured completely and is closed toward the end of the procedure.**

Uretero-Neobladder Anastomosis

The left ureter is transposed to the right side by creating a tunnel under the sigmoid mesentery. The Bricker anastomosis is performed between the ureters and the afferent limb. During the Wallace anastomosis, the ureters are spatulated and joined at the posterior walls of the ureters. The stents can be externalized through the midline just above the pubic symphysis or internalized by using double-J stents.

Closure of the Neobladder

The remaining part of the reservoir is closed once ureters are implanted with stents, and the 22 Foley catheter is placed.

Modified Studer Neobladder: The USC Institute of Urology Technique

Configuration and Setup

A total of 65 cm of ileum are used for the modified Studer neobladder technique (44 cm for the pouch, 16 cm for the chimney, and 5 cm are discarded to allow for ease of ileoileal anastomosis without the need for deep mesenteric division) (Fig. 142.5; Chopra et al., 2017). It is critical to identify the most dependent and mobile part of the ileum for tension-free neobladder-urethral anastomosis and is tagged to become the site of the neobladder-urethral anastomosis. Eleven centimeters of bowel are tagged distally toward the ileocecal valve and become the site of bowel division. After the neobladder-urethral anastomosis site is marked, proximally 33 cm are tagged and remaining proximal 16 cm are also tagged to become the future chimney (afferent limb) for the uretero-neobladder anastomosis.

FIG. 142.5 Illustrated schema of key steps in creating the USC modification of Studer neobladder. *1,* 65 cm of ileum are isolated and used for this technique (44 cm for the pouch, 16 cm for the chimney, and 5 cm

are discarded). It is critical to identify the most dependent and mobile part of the ileum for tension-free urethro-neobladder anastomosis. *2,* 33 cm is tagged for neobladder, and proximal to this, 16 cm are left intact for the future chimney (afferent limb) for ureteroileal anastomosis. *3,* Detubularization is done and the posterior plate is aligned and sutured. *4,* The posterior plate is rotated 90 degrees counterclockwise to align the previously marked urethro-neobladder anastomosis site at the first 11-cm point. *5,* Anastomosis is performed over a 24-Fr hematuria catheter. The lateral walls are aligned and sutured. *6,* The crossed left and the right ureters are spatulated and anastomosed using the Bricker technique with ureteral stents. Once the stents are functional and the catheter is checked, the remaining pouch (anterior suture line) is closed.

Using a 24-Fr chest tube, approximately 44 cm of bowel is incised in its most antimesenteric point, and the staple lines are removed at the ends. The medial edges of the opened ileal segments are aligned by four interrupted sutures and closed using 2-0 V-Loc sutures. The USC group prefer to use the shortest (6 inches) length of barbed suture to increase the efficiency of suturing.

Rotation of Pouch, Neobladder-Urethral Anastomosis, and Cross-Folding of the Pouch

The posterior plate is rotated 90 degrees counterclockwise to align the previously marked neobladder-urethral anastomosis site at the first 11-cm point. A maneuver similar to the “Rocco” stitch is used to assist in suturing the distal posterior Denonvilliers fascia to reduce the tension on the anastomosis. A double-armed Monocryl suture on an RB1 needle is used to perform anastomosis over a 24-Fr hematuria catheter. The remaining pouch is closed using a running 2-0 V-Loc suture.

Uretero-Neobladder Anastomosis

The left ureter is transferred underneath the sigmoid colon. The two ureters are spatulated; double-J stents are placed and anastomosed using the Bricker technique. Once the stents are functional and the position of the catheter is checked, the anterior suture line is closed.

The USC group recommends several surgical maneuvers and tricks to facilitate the procedure and reduce operative time. They include the use of 11 cm premeasured stitch to isolate bowel, color-coded stay sutures for orientation, stay sutures for traction-counter traction, and use of short length of V-Loc suture for sewing the neobladder.

Pyramid Neobladder: The University College London Hospital Technique

Configuration and Setup

This detubularized cross-folded neobladder is based on the technique adapted from Koie (Koie et al., 2006). The pyramid configuration was developed to simplify the creation of the pouch (Fig. 142.6; Tan et al., 2015). A 50-cm segment of bowel is identified with the most dependent part connected to the urethra.

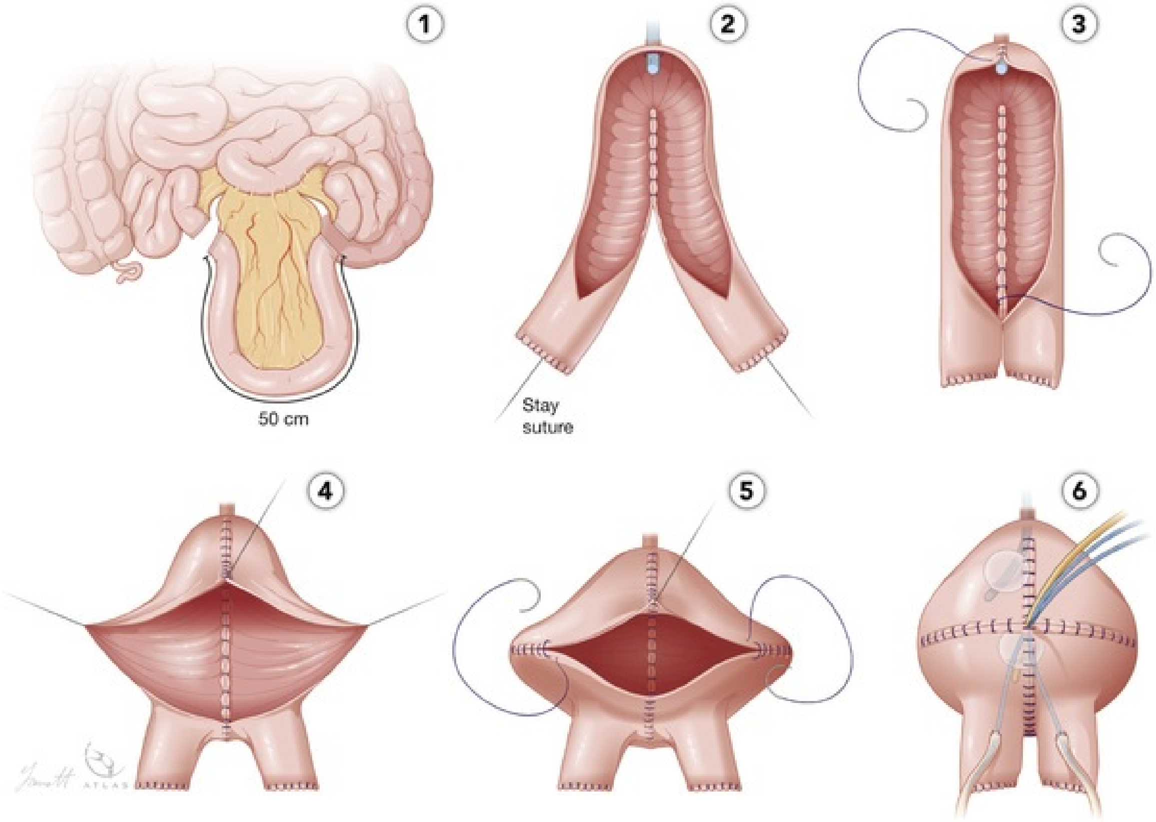

FIG. 142.6 Illustrated schema of key steps in creating the Pyramid neobladder. *1,* A 50-cm segment of bowel is identified and isolated. *2,* The dependent part of ileal segment is detubularized at its antimesenteric boundary followed by two stay sutures, 25 cm from each limb. The most dependent part is connected to the urethra creating the urethro-neobladder anastomosis. *3,* The posterior plate is closed using a 3-0 V-Loc suture. After this the anterior plate is closed up to 10 cm from the pubic symphysis. *4,* Two lateral stay sutures are placed midway along the remaining bowel segment. *5,* At this point the bowel segments are closed from lateral to medial direction in a coronal plane. *6,* The ureters are spatulated and

anastomosed to the short limbs on their respective sides over ureteral stents. The authors externalize the stents and insert a suprapubic tube.

Formation of the Pyramid Neobladder

Once neobladder-urethral anastomosis is completed, the dependent part of ileal segment is detubularized at its antimesenteric boundary followed by placement of two stay sutures 25 cm from each limb. The posterior plate is closed using a 3-0 V-Loc suture. After this, the anterior plate is closed up to 10 cm from the pubic symphysis. Two lateral stay sutures are placed midway along the remaining bowel segment. At this point the bowel segments are closed from lateral to medial direction in a coronal plane.

Uretero-Neobladder Anastomosis

The ureters are spatulated and anastomosed to the short limbs on their respective sides over ureteral stents. The authors externalize the stents and insert a suprapubic tube for irrigation and safety.

Modified Y Neobladder: The Clinique Saint-Augustin Technique

Configuration and Setup

For the modified Y neobladder using the Clinique Saint-Augustin technique, a 40-cm ileal segment is isolated approximately 20 cm from the ileocecal valve (Fig. 142.7; Asimakopoulous et al., 2016). The most dependent part is arranged in a modified Y shape and brought down to the urethra for a tension-free anastomosis. The antimesenteric part is incised and anastomosed to the urethra.

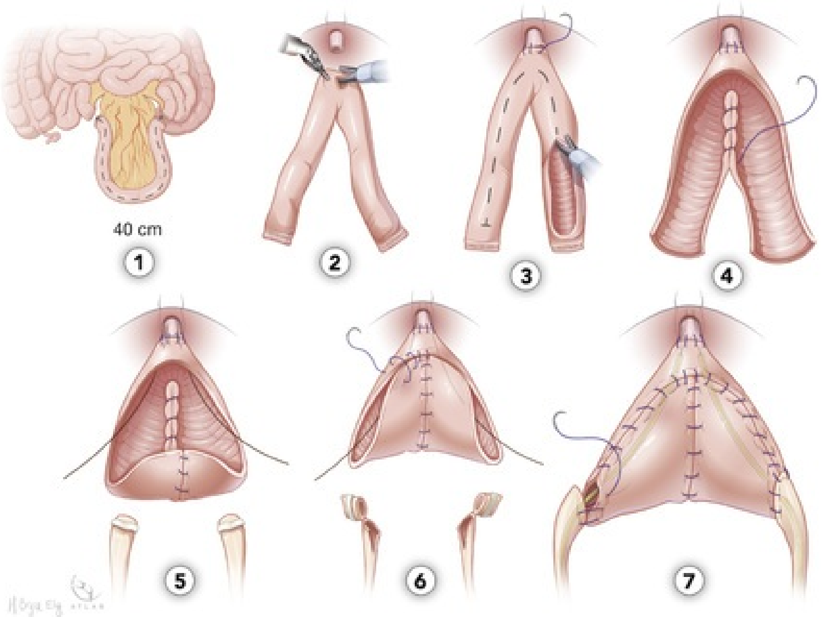

FIG. 142.7 Illustrated schema of key steps in creating the Clinique Saint-Augustin Y neobladder. *1,* A 40-cm ileal segment is isolated approximately 20 cm from the ileocecal valve. *2,* The most dependent part is arranged in a modified Y shape and brought down to the urethra for a tension-free anastomosis. *3,* The antimesenteric border is incised. *4,* The incised ends of the two limbs are connected, and the posterior plate is created. *5 and 6,* Subsequently, the anterior reconstruction of the neobladder is started. The ureters are spatulated and not crossed over. *7,* The ureters are directly anastomosed to the open ends of the neobladder in a refluxing fashion. A 20-Fr Mercier catheter is placed with two hydrophilic guidewires to assist with stent placement. The anterior wall is then closed.

Creation of the Neobladder

The incised ends of the two limbs are connected and the posterior plate is created. Subsequently the anterior reconstruction of the neobladder is performed. A 20-Fr Mercier catheter with two hydrophilic guidewires is placed to assist with stent placement later in the procedure.

Uretero-Neobladder Anastomosis

The ureters are spatulated and directly anastomosed to the open ends of the neobladder in a refluxing fashion in their respective sites. The two single-J stents are placed via the urethra using the Mercier catheter and the preplaced hydrophilic wires.

Padua Neobladder

Configuration and Setup

For the Padua neobladder, approximately 42 cm of ileum is selected at least 20 cm from the ileocecal valve (Fig. 142.8; Simone et al., 2016). The neobladder is isolated with only one stapler load at the proximal end and two stapler loads at the distal end. The isolated bowel is marked approximately 12 to 14 cm proximal to the distal end for the neobladder-urethral anastomosis to ensure a tension-free anastomosis. The proximal half of the separated bowel is used for configuring the left base and the dome of the neobladder.

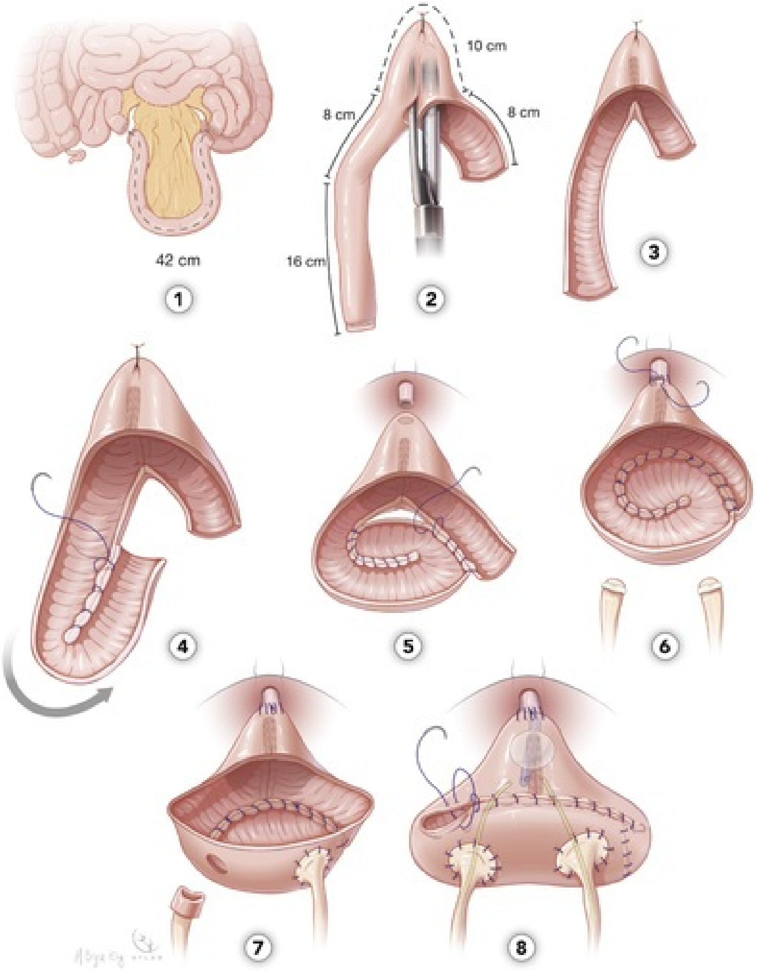

FIG. 142.8 Illustrated schema of key steps in creating the Padua neobladder. *1,* Approximately 42 cm of ileum (8 cm right plate, 10 cm neck configuration, 8 + 16 cm left plate) is folded in U configuration. *2,* The tension-free neobladder neck is identified about 12 to 14 cm proximal to the distal ileum and tagged with a suture. After detubularizing 8 cm of distal

ileum along the anti-mesenteric border, the surgeon introduces a stapler through the inverted U to create the neobladder neck. *3,* The remaining 24 cm of the ileum is subsequently detubularized starting at the proximal ileal edge. *4,* The proximal half of the loop helps in the first folding to configure the left base and the dome of the neobladder. *5,* The second folding helps in configuring the posterior plate of the neobladder. *6,* The 16-cm folded segment and the right plate align to create the posterior plate of the neobladder. The urethroileal anastomosis is performed and a 22-Fr hematuria catheter is inserted. *7,* The ureters are passed through the posterior aspect of the neobladder and spatulated and ureteroileal anastomoses (modified split-nipple technique) are performed. *8,* The anterior wall is closed.

A 10-cm inverted U-neobladder neck is created with a stay suture approximately 8 and 18 cm from the distal ileum. After the 8 cm is detubularized, the bladder neck is created by firing a stapler. The remaining 24 cm are detubularized, the most distal 8 cm is folded, and the edges are joined for creating the future dome of the neobladder. The subsequent fold is used to configure the posterior plate.

Uretero-Neobladder Anastomosis

The ureters are passed through the posterior aspect of the neobladder, spatulated, and the anastomosis is performed according to the modified split-nipple technique. The closure of the anterior plate provides the final shape to the neobladder.

Florin: Florence Robotic Intracorporeal Neobladder

Configuration and Setup

For the Florence robotic intracorporeal neobladder, a 50-cm segment of ileum approximately 20 cm from the ileocecal valve is chosen (Fig. 142.9; Minervini et al., 2018). The neobladder-urethral anastomosis (using a 20 Foley catheter) is used to create an asymmetrical U shape (30 cm distally and 20 cm proximally) between the urethra and the segment of bowel. The ileum segment is entirely detubularized and the posterior plate is reconfigured as an L to create a neo-trigone (widen posterior support of the neobladder). After the completion of the posterior plate, the neobladder neck is reconstructed by suturing the anterior wall of the neobladder (2–5 cm anteriorly and proximal). The posterior plate is folded anteriorly to create two symmetrical segments. The length of the neobladder neck is adjusted based on the capacity of the posterior plate to reach anterior aspect of the anastomosis.

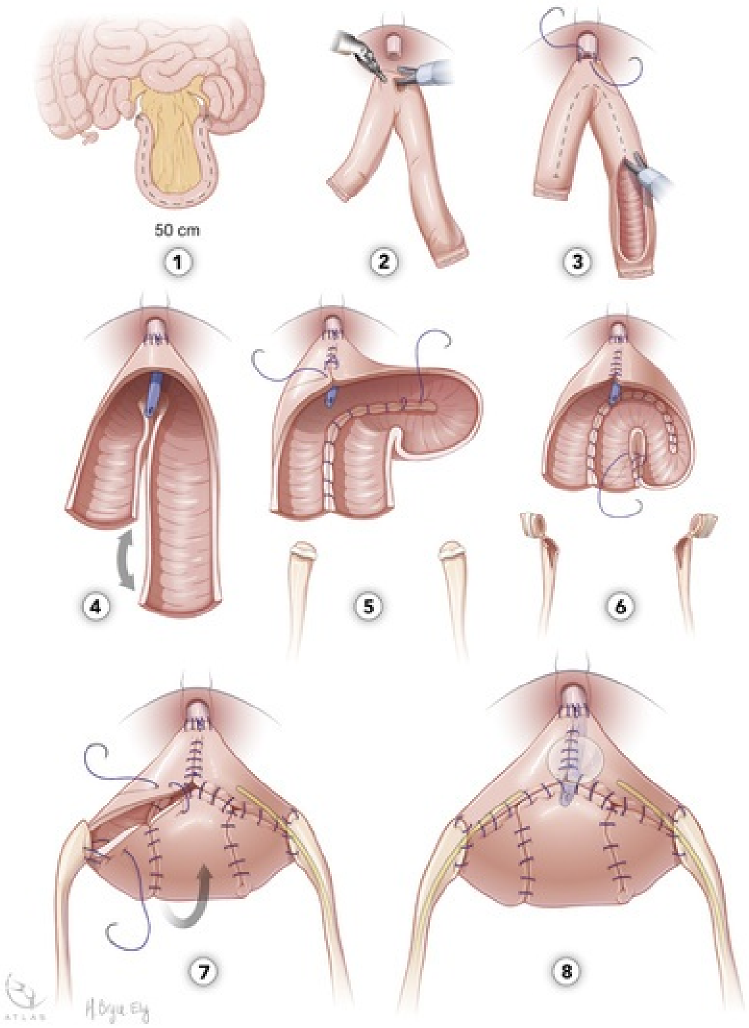

FIG. 142.9 Illustrated schema of key steps in creating the FloRIN neobladder. *1,* A 50-cm segment of ileum approximately 20 cm from the ileocecal valve is chosen. *2,* The neobladder-urethral anastomosis is performed and utilized to create an asymmetrical U shape (30 cm distally and 20 cm proximally). *3,* The ileum segment is entirely detubularized. *4,* The posterior plate is reconfigured as an L to create a neo-trigone. *5,* The neobladder neck is reconstructed by suturing the anterior wall of the neobladder (2–5 cm anteriorly and proximal). *6,* The posterior plate is folded anteriorly to create two symmetrical segments. The distal ends of the ureter are spatulated. *7,* Re-implanted in an antireflux technique on the lateral side of each anterior aspect of the neobladder. *8,* Once the single-J ureteral stents are secured in place, the anterior plate is finally closed in an inverted V-shaped manner.

Uretero-Neobladder Anastomosis

The distal ends of the ureter are spatulated and reimplanted in an antireflux technique on the lateral side of each anterior aspect of the neobladder. Once the single-J ureteral stents are secured in place, the anterior plate is finally closed in an inverted V-shaped manner.

Modified “W” Hautmann Neobladder: The Roswell Park Comprehensive Cancer Center Technique

Configuration and Setup

For the modified “W” Hautmann neobladder, a 45- to 50-cm bowel segment is chosen for the neobladder and divided into right and left troughs (Fig. 142.10; Hussein et al., 2017a). Each trough has a descending and an ascending loop with a chimney. Four stay sutures (Tags A-D) are used to fix the W configuration. The first stay suture (Tag A) should be at the most dependent portion of the right trough. The second stay suture is placed 12 to 15 cm proximal to the first and marks the upper end of the right trough (Tag B). The third suture is placed to create the left trough (Tag C). The fourth stay suture (Tag D) marks the upper end of the left trough.

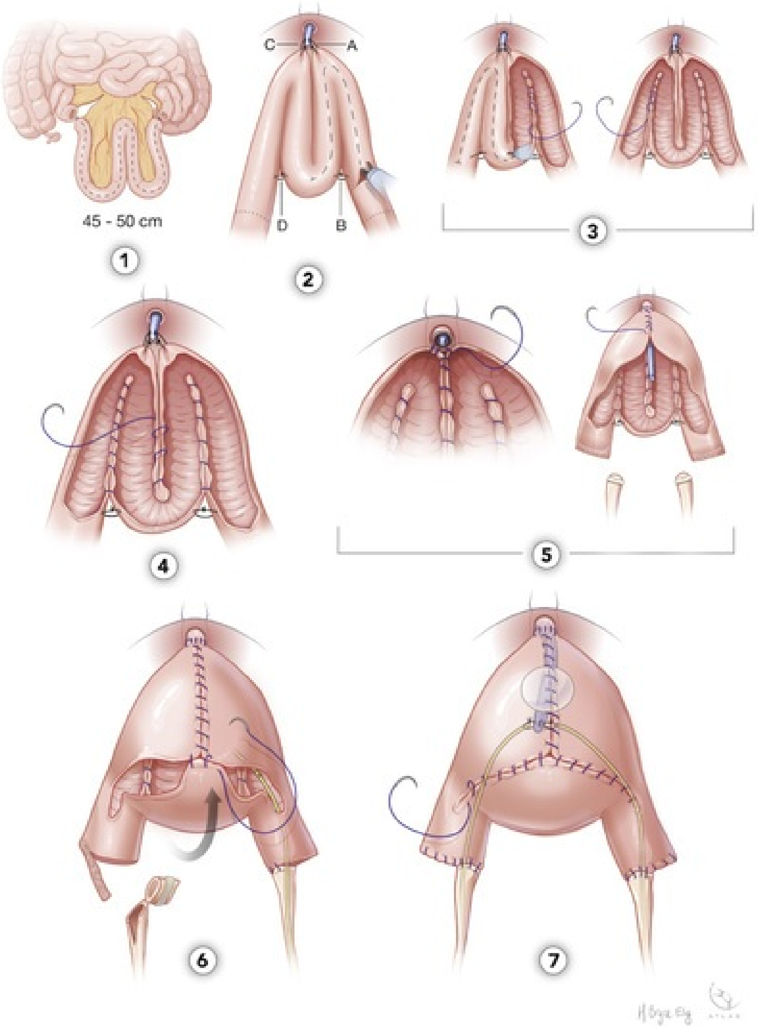

FIG. 142.10 Illustrated schema of key steps in creating the W neobladder. *1,* 45–50 cm of bowel is isolated 12 to 15 cm from the terminal ileum. *2,* The identified bowel is extended into the pelvis and tagged to the tip of the Foley catheter that serves as a marionette (*A* and *C*). Two holding sutures (*B* and *D*) are placed, which complete and stabilize the W configuration of the neobladder. *3,* The right limb is incised along the antimesenteric border, avoiding the afferent limb of the neobladder. Suturing the opposing sides of the incised bowel creates the right trough. Avoid incising both the troughs simultaneously while suturing maintains orientation and spillage of bowel content. *4,* Once both troughs are created, the edges are joined in the middle to develop the posterior plate of the neobladder. *5,* The neobladder urethral anastomosis is completed and the anterior wall closure is started. *6,* The staple lines are excised off the proximal limbs, the ureters are anastomosed directly, and single-J stents/feeding tubes are placed and distally sutured to the Foley catheter. *7,* The final closure of the neobladder is accomplished by completing the inverted T closure of the neobladder.

Creation of the Neobladder

Excluding the 5-cm chimney, the right trough is first detubularized, incised, and sutured to avoid gross spillage of bowel contents and maintain orientation. This can be performed by making an enterotomy cranially then cutting through it (preferably using hot scissors) while exerting traction with bipolar grasper and counter traction using the suction device. The detubularization incision is made a few millimeters away from the mesenteric border to provide a wider bowel surface area when closing the neobladder anteriorly. After detubularization of the right trough, the mesenteric edges of the bowel are sutured together using a series of 3-0 V-Loc suture. Suturing is started caudally and continues cranially while exerting traction on the bowel using the fourth arm. To speed up suturing, the continuous suture line can be tightened at every third throw. The same process is then repeated for the left trough. The right and left troughs are then sutured together to create the posterior plate.

After release of the stay sutures (Tags A and C), the most dependent part of the posterior plate of the neobladder is anastomosed to the posterior urethral plate using a 3-0 V-Loc suture. The anterior part of the anastomosis is then completed over a 22-Fr silicone catheter. Closure of only the lower half of the anterior wall of the neobladder is subsequently performed.

Uretero-Neobladder Anastamosis

The staple line of the right chimney is removed and the opening is sutured (3-0 Vicryl). An enterotomy is made on the anterior aspect of the chimney for an end-to-side ureteroileal anastomosis. The fourth arm is used to steadily retract the cut Hem-o-lock clip end at the distal ureter. The ureter is partially transected and spatulated using robotic scissors for a wide anastomosis. A single-armed 4-0 Vicryl suture (5 cm long) is used to make an anastomosis with interrupted sutures (or double armed for a continuous anastomosis). Either way, the first anchoring stitch should be placed in an “outside-in” manner on the ureter side at the angle of the spatulation. The suture on the neobladder side is placed “inside out.” After placing the first stitch, the fourth arm is manipulated to bring the ureteral end close to the enterotomy before tying the stitch to achieve a tension-free anastomosis. This initial suture ensures proper alignment and placement of the subsequent sutures. Once the first suture is placed, the remaining anastomosis can be completed. Once the posterior wall anastomosis is completed, the ureteral stent/feeding tube is placed. A metal laparoscopic suction tube is gently advanced through the 15-mm assistant port or the urethral 22 coudé hematuria catheter, through open part of the anterior wall of the neobladder. The metal suction tip is held in place by the robotic needle driver to allow passage of stent into the chimney and then into the ureter. An 8.5-Fr, single-J ureteral stent or a pediatric feeding tube with a guidewire is passed through the suction tip and fed into the ureteral opening. Once the stent is pushed all the way, the suction tip is withdrawn while the holding the stent. A single-J stent is preferred to have a sufficient length to fix the stent distally near the neourethra or to the Foley. A 3-0 chromic suture is used to secure the stent to the neobladder to prevent dislodgement, and another stitch can be used to secure the distal end of the single-J stent near the neourethra or to the Foley catheter (to facilitate stent removal later). The anterior half of the uretero-neobladder anastomosis is completed. The anastomosis of the left side is performed in a similar fashion.

The remaining anterior neobladder wall is closed using 3-0 V-Loc suture in a T-shaped manner. The Foley catheter is used for irrigation. A Jackson-Pratt or Blake drain is left in place.

Restoration of the Bowel.

A short suprapubic port is inserted for ease of alignment of bowel re-anastomosis. A 60-mm Endo GIA stapler is inserted through the short 12-mm suprapubic port. A side-to-side anastomosis is performed once both ends of the bowel are aligned along their antimesenteric borders. The open ends of the two anastomosed intestinal segments are stapled by firing an endo GIA stapler horizontally via the right assistant port. A secure stay suture is placed to reduce tension and support the edge of the anti-mesenteric border. The mesentery window is closed using a 3-0 silk suture.

Maneuvers Facilitating Neobladder-Urethral Anastomosis.

A tension-free neobladder urethral anastomosis is critical and is one of the most challenging operative steps during intracorporeal neobladder. This is a key step, especially when the patient is in a steep Trendelenburg position; the amount of stretch that can be used with lack of tactile feedback has to be kept in balance. Various steps have been proposed to facilitate with neobladder-urethral anastomosis. As discussed earlier, preservation of the dorsal venous complex and the length of urethra are critical. The ability to cut the dorsal venous complex without initially suturing helps in releasing and opening the apex for maximal urethral preservation and avoids apical margins (Guru et al., 2009b). Several other key steps include mobilizing the sigmoid colon out of the true pelvis, and occasionally a stay suture is used to keep it temporarily fixed laterally until the neobladder is created.

It is also critical to reduce the steep Trendelenburg position after undocking the robot. The new advances with the da Vinci Xi Surgical Systems with an integrated operating room table make this easier without undocking the surgical robot. Application of perineal pressure at the time of anastomosis with insertion of a Foley catheter to guide the needle toward the urethral opening has already been used consistently during robot-assisted radical prostatectomy. The use of barbed suture, especially the V-Loc, has helped reduce the time and complexity of neobladder creation as well as the urethral anastomosis. Detubularization of the ileal segment, opening, and stretching of the bowel help in adding length to the ileum. The peritoneal covering of the ileum can be also incised, and the mesenteric fat is released to help add length. This should be performed with care because it exposes the mesenteric vessels and can lead to annoying bleeding, which can jeopardize the vascular supply to the neobladder (Almassi et al., 2016). The Karolinska group has used Penrose drains in their early experience for gentle stretching and traction of bowel for ease of anastomosis (Collins et al., 2014).

Robot-Assisted Intracorporeal Continent Cutaneous Diversion

Colon Mobilization, Isolation, and Ileocolic Anastomosis

For robot-assisted intracorporeal continent cutaneous diversion, after cystectomy and lymph node dissection, the right colon is mobilized from the mid-transverse colon to the ileocecal junction (Desai et al., 2017). Two stay sutures (at the cecum and hepatic flexure) are placed to facilitate handling and maintain anatomic orientation. The greater omentum is incised, and the proximal transverse colon is mobilized from the duodenum and retroperitoneal structures. The hepatic flexure is freed from the Gerota fascia by incising the hepatocolic ligament. Dissection continues toward the cecum by incising the white line of Toldt. The terminal ileum is transected 15 cm proximal to the ileocecal junction. Subsequently the transverse colon is transected between the hepatic flexure and the middle colic artery. Ileocolic continuity is restored immediately after this step to avoid malrotation (Fig. 142.11).

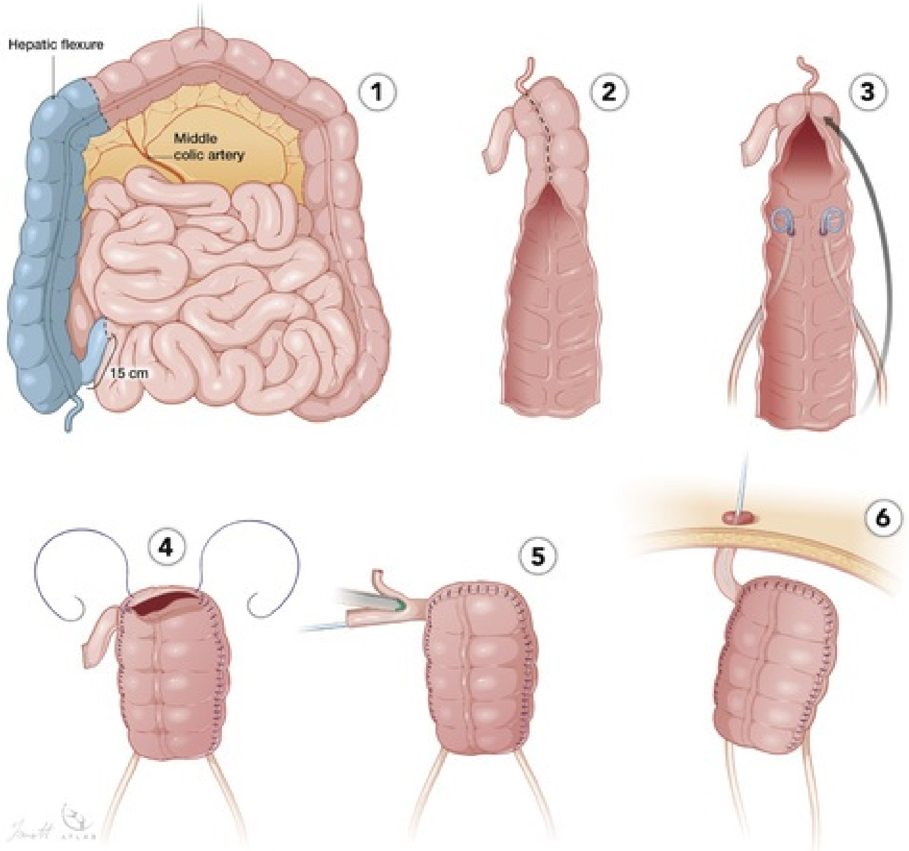

FIG. 142.11 Illustrated schema of key steps in creating the robot-assisted intracorporeal Indiana pouch. *1,* The cecum and ascending colon are isolated by transecting the terminal ileum (15 cm proximal to ileocecal junction) and the transverse colon between the hepatic flexure and the middle colic artery. *2,* The staple line of the colon is excised and the segment is detubularized. *3,* The left ureter is transferred below the sigmoid mesentery. Both ureters are spatulated, delivered through the posterior colonic plate, and anastomosed (double-J stents). *4,* The detubularized colon is folded vertically by connecting the distal end of incised colon with the angle of the ileocecal valve. *5,* A 14-Fr Foley catheter is inserted through the ileum into the colon. The terminal ileum is tapered at the antimesenteric border using staplers. *6,* The edges of the spatulated and tapered ileum are attached to the umbilical skin and fashioned into a stoma.

Creation of the Colonic Pouch

The base of the appendix is resected. The isolated colon pouch is irrigated and cleared with a hematuria catheter through the opening into the cecum. The staple line of the colon is excised and the right colon is detubularized along the anterior tenia coli. The detubularized colon is folded vertically by connecting the distal end of incised colon with spatulated aspect of the ileocecal valve. The posterior suture line is closed first using 2-0 Vicryl and continuous barbed V-Loc.

Uretero-Colonic Anastomosis

The transferred left and the right ureters are spatulated and are delivered through the posterior colonic plate and anastomosed using 4-0 or 5-0 Vicryl sutures. The anastomosis is stented using double-J stents. A 24-Fr Rusch catheter is introduced through the right lateral port as a cecostomy tube and inserted into the pouch through the appendiceal stump. The cecostomy tube is secured with a 2-0 Vicryl purse-string suture into the cecal wall. The anterior suture line is closed in a similar fashion to the posterior.

Tapering of the Ileum and Imbricating the Ileocecal Valve

An Allis clamp is inserted via a 2-cm V-shaped skin flap, and the end of the terminal ileum is exteriorized through the umbilical incision. A 14-Fr Foley catheter is inserted through the ileum into the colon. After proper positioning of the catheter, the ileum is reinserted into the abdomen. The terminal ileum is stretched over the catheter, and the excess antimesenteric portion is excised using serial fires of staplers. The ileocecal valve is reinforced by a series of interrupted 3-0 Vicryl imbricating sutures. The edges of the spatulated and tapered ileum are attached to the umbilical skin to fashion the stoma.

Postoperative Care

Optimizing fluid balance and avoiding overhydration should help manage fluid shifts in this patient population mostly with advanced age. Cochrane meta-analysis revealed no advantage to leaving nasogastric tube after surgery (Nelson et al., 2007). Pelvic drainage is preferred; we use a Blake drain for neobladders and a Foley via the urethra as a drain for ileal conduits (removed on postoperative day 1). Adequate pelvic drainage and stenting of ureters especially at the anastomosis has already been shown to help in bowel recovery and reduce metabolic acidosis. Some authors have shown the feasibility of ureteroileal anastomosis without stents for ileal conduits (Tan et al., 2017). Drains can be removed usually when output is reduced. **The urethral catheter**

in neobladders can be removed approximately 3 to 4 weeks postoperatively once absence of any leak is established on pouchogram. The ureteral stents, if exteriorized to skin, are removed a week after surgery. If the stents are internalized, it is recommended to remove the double-J stents with cystoscopy at 3 to 4 weeks when the neobladder has healed. We have started using pediatric feeding tubes more often and attaching them to the urethral catheter and removing them once the pouchogram is acceptable without the need for cystoscopy. The disadvantage of this method is the loss of attached stents across the anastomosis in case the Foley slips out. Irrigation with saline of the neobladder is recommended every 8 hours to avoid mucus plugging and catheter blockage.

Key Points

- Optimizing fluid balance and avoiding overhydration should help manage fluid shift in this patient population with advanced age.
- Adequate pelvic drainage and stenting of ureters especially at the anastomosis has shown to help in bowel recovery and avoid metabolic abnormalities.
- Irrigation of the neobladder is recommended every 8 hours to avoid mucus plugging and catheter blockage.

Outcomes

ICUD attempts to minimize bowel manipulation and reduce postoperative pain with minimal wound retraction and smaller incisions. **Several factors have facilitated performance of the procedure with an intracorporeal technique. First, RARC and extended PLND technique have been standardized with oncologic results equivalent to standard open techniques. Second, the robot-assisted surgical platform with improving console-based surgical skills have allowed the robotic surgeons to optimize use of this technology.** The advantage of the endo-wrist technology in robot-assisted surgery allows surgeons to use the mechanical wrist for suturing and reconstructive purposes with minimal effort in comparison with conventional laparoscopy. This section addresses various key factors that define the acceptance of ICUD based on operative time, learning curve, complications, functional outcomes, and comparing outcomes of intra- and extracorporeal urinary diversions after RARC.

Operative Time

One of the major limitations of incorporating ICUD has been prolonged operative time (Balaji et al., 2004; Hubert et al., 2006). Operative time for all techniques is presented (ranges between 305 to 420 minutes) in Table 142.1.

Prolonged operative times for radical cystectomy have been associated with higher incidence of complications and perioperative mortality independent of the disease stage or associated comorbidities (Lavallee et al., 2014). Not surprisingly, operative time has been identified as a quality measure for surgical performance for RARC (Hussein et al., 2016a). Patients have multiple confounding factors that contribute to variation in operative time for RARC, including patient demographics and comorbidities, disease stage, procedural complexity, technical modifications, surgeon experience, and hospital volume (Filson et al., 2016).

In a study from IRCC comprising 2134 RARCs, median operative time was 364 minutes (interquartile range [IQR] 300–446). There was a trend toward shorter operative times for RARC, decreasing from a mean of 371 minutes in 2006 to 323 minutes in 2015. The variable most strongly associated with surgical time was the type of diversion, and it resulted in the largest mean difference (ileal conduits were 70 minutes shorter than neobladders) (Hussein et al., 2017b).

Shorter operative times have been demonstrated in older patients with multiple comorbidities. Surgeons are usually concerned of the potential higher anesthetic complications in older and sicker patients. Female patients were also found to have longer operative times (possibly because of performance of hysterectomy and vaginal reconstruction) (Filson et al., 2016). Higher body mass index and prior abdominal surgery add to the complexity of RARC, with more time spent in port placement, careful dissection, and lymph node dissection (Yuh et al., 2009). No significant difference between intracorporeal and extracorporeal approaches to urinary diversion was found. One possible explanation is that the additional time for undocking, patient positioning, and then re-docking for extracorporeal diversion may have reduced the difference between approaches (Hussein et al., 2017b).

High-volume institutions had shorter operative times for radical cystectomy. This may be attributed to the experience of the surgeon and the teams at those institutions (Filson et al., 2016; Hussein et al., 2017b). The cutoff for surgical proficiency for RARC was higher in a study conducted by IRCC than previously reported (22 RARCs) (Hayn et al., 2010). Surgeons who had performed at least 66 RARCs saved an average of 55 minutes of operative time among patients who underwent ileal conduits (Hussein et al., 2017b). This highlights the importance of fellowship training and dedicated cystectomy programs, in which surgeons can increase their RARC volume (Guru et al., 2009a).

Learning Curve

Collins et al. (2014) evaluated the learning curve of intracorporeal neobladders and found that overall operative times and the risk of conversion reduced from 30% to 10% after only 10 consecutive procedures. Reduction in complications was observed in early (70% to 30%) ($P < 0.05$) and late (50% to 0) ($P = 0.01$) categories as the surgeons gained experience with intracorporeal neobladder. The USC group has also shown reduction in operative time by keeping the console surgeon consistent and shown almost a more than 50% reduction (9.3 to 4.7 hours) (Desai et al., 2017). **Mentoring effect was helpful in reducing overall operative time and avoided open conversion during early experience. Conversion of an intracorporeal neobladder to open was associated with an increase in overall length of stay.**

Complications

The majority of the reported complications are attributed to urinary diversion; this part of the procedure is associated with most changes postoperatively. **The possible attributed advantages of a minimally invasive approach are in terms of reduced bowel manipulation, decreased insensible losses, and minimal need for analgesia, which can help reduce the significant morbidity of this procedure.**

The majority of studies reported either modified Dindo-Clavein or the modified Memorial Sloan Kettering classification for complications and reported complications up to 3 months after surgery (Table 142.2). Based on current literature focused on ICUD, overall early (30-day) and late (90-day) complications range from 22% to 63% and 5% to 81%, respectively (see Table 142.2). High-grade complications were observed in up to 37%, and **infections were the most common cause of these complications.** However, it is critical to assess complication beyond 90 days, as the Roswell Park group showed that the majority (two-thirds) of significant complications requiring reoperations occurred after 3 months of surgery (Hussein et al., 2016a)

Reoperations After Robot-Assisted Radical Cystectomy

The majority of reoperations for patients who undergo radical cystectomy are related to urinary diversion, especially in the late follow-up period. In my series of more than 400 consecutive procedures, the rate of surgical intervention was 23% after a mean follow-up of 27 months. The mean time to any surgical intervention was 14 months, and 68% of these were performed after 90 days. The reoperation rates were 30% and 46% at 2 and 5 years, respectively.

Neoadjuvant chemotherapy and any high-grade complication after surgery were predictors of surgical intervention after robot-assisted radical cystectomy (Hussein et al., 2016b).

Uretero-Enteric Strictures

Despite meticulous dissection and minimal manipulation, my intracorporeal ileal conduit technique demonstrated higher stricture rates. The prevalence rates were 12%, 16%, and 19% at 1, 3, and 5 years after RARC. Since then, we have abandoned the slitlike enterotomy using the thermal hook and now advocate an athermal, buttonhole enterotomy with removal of the serosa and also retroperitonealize the proximal anastomotic site (Ahmed et al., 2017). The initial experience with robot-assisted revision of ureteroileal strictures showed that open and robot-assisted approaches are comparable in terms of perioperative outcomes (Ahmed et al., 2017; Dangle and Abaza, 2012). Several other surgeons have shown comparable results between the two approaches. Use of indocyanine green dye during robot-assisted ureteral reconstruction has proven to guide accurate identification of the ureter and precise visualization of ureteral strictures (Lee et al., 2015).

Fistula and Bowel Obstruction

In the author's experience the 2-year fistula rate was 3%, and approximately half of the patients were repaired using a robotic interface. Meanwhile, 3% required surgical intervention for bowel obstruction. The rates of intervention for bowel obstruction were 5% and 12% at 2 and 5 years, respectively (Hussein et al., 2016a).

Abdominal Wall–Related Complications

The surgical intervention rate for abdominal wall–related complications was 3% at 2 years. The causes for these interventions included hernias (para-stomal and incisional), adhesions, and wound dehiscence (Hussein et al., 2016a). Twenty percent of parastomal hernias were seen in patients who underwent RARC and ileal conduit after a median time of 13 months after surgery. The rates of developing a parastomal hernia were 9%, 23%, and 32% at 1, 2, and 3 years, respectively. Symptoms only developed in one-third patients, of whom only 15% required surgical intervention. Longer operative times, larger fascial defect (greater or equal to 30 mm), and a lower estimated glomerular filtration rate (poor healing) were significantly associated with the risk of developing parastomal hernia. The Roswell Park group has shown feasibility and durability of robot-assisted parastomal mesh hernioplasty. The operative time was longer (456 minutes vs. 389 minutes) during the initial experience (Hussein et al., 2018).

Functional Outcomes

Continence After Creation of Neobladder.

Radical extirpation of the bladder results in unavoidable consequences resulting from loss of vesicourethral reflex. This leads to a disconnect between the reservoir and the urinary sphincter and deactivation of the spinal reflex, resulting in the inability to have any desire to void. The key events leading to voiding in such scenarios are exposure of urine to sensory mechanism in the posterior urethra, leading to initiation of urethral voiding in patients with intact pudendal nerves. The functional urethro-sphincteric guarding reflexes help activate the contractions of the urinary sphincter and ultimately helps avoid daytime leakage. During the night, especially in deep sleep states, the inactivation of the guarding reflex leaves continence at the mercy of the functional capacity of the urinary reservoir. The ideal surgical maneuvers should focus on adequate detubularization and capacity, leading to compliance and preservation of the urethral sphincter complex (Koraitim et al., 2006).

The factors leading to urinary incontinence after urinary diversion are multifaceted (age, volume and shape of reservoir, functional length of urethra, and nerve supply). It is ideal to evaluate patients' urinary function recovery 6 months to a year after surgery once the neobladder has acquired its maximum capacity (Hautmann, 2003). It is ideal to keep the functional capacity lower than the nocturnal urinary output; use of an alarm at night is recommended until the bladder fullness sensation is recognized (Studer and Zingg, 1997).

Patients also have to understand that up to 25% of men may end up using self-intermittent catheterization for incomplete emptying (Steers, 2000). The intracorporeal neobladders currently published have shown up to 11% patients have a need for self-catheterization (Table 142.3). The range of daytime continence varies from 68% to 100%, and nighttime incontinence has been reported between 55% and 85% (see Table 142.3). Predictive features for favorable continence after open surgery have been found to be good preoperative Eastern Cooperative Oncology Group status, subjective retained sensation of bladder-filling questions (Kretschmer et al., 2017).

Intracorporeal Versus Extracorporeal Diversion

Based on a previous study by the IRCC (Ahmed et al., 2014), only 8 of 18 institutions had performed ICUD. Readmission rates at 30 days (5% vs. 15%, $P \leq 0.0001$) and 90 days (12% vs. 19%, $P = 0.01$) were lower in the intracorporeal group. Blood transfusions were significantly lower in the intracorporeal group (7% vs. 16%, $P = 0.02$). Gastrointestinal-related complications were significantly lower in the intracorporeal group (10% vs. 23%, $P < 0.001$), supporting the notion of minimal bowel manipulation and open bowel exposure may help in lowering complications and possibly help with early recovery. Mortality at 90 days was lower in the intracorporeal group (1.6% vs. 4.9%, $P = 0.04$) possibly because of patient selection bias and surgeon experience.

A more recent update from IRCC (51% ICUD, $n = 1094$) showed that patients who received ICUD had shorter operative time and required fewer blood transfusions compared with ECUD. Although they experienced more high-grade complications (13% vs. 10%, $P = 0.02$), which decreased over time. On multivariable analysis, the approach to urinary diversion was not significantly associated with high-grade complications or readmissions. Several factors were associated with receiving ICUD in this series; healthier patients (with American Society of Anesthesiologists score less than 3), high-volume institutions, and more recent cystectomy era (2013–2016) compared with earlier experience were all significantly associated with receiving ICUD (Hussein et al., 2018).

Future Directions

After the safe inclusion of RARC and lymph node dissection in our armamentarium, ICUD is now performed worldwide. The incorporation of ICUD should be done in a stepwise fashion from ileal conduits to neobladders. It is vital to understand the anatomic, pathophysiologic, and technical nuances of ICUD to prevent long-term complications and upper tract failure. A permanent place for ICUD in urologic surgery will depend not only on optimal operative times but also on optimization of pathophysiologic functions of neobladder and therefore reduction in morbidity and quicker return of quality of life. These parameters have to be proven in comparison with the standards set with open urinary diversion. No randomized controlled trial (RCT) has investigated whether one approach of urinary diversion is preferred. A randomized controlled study is currently in progress in the UK comparing RARC with ICUD versus open radical cystectomy (iROC), which may answer the question of whether ICUD confers additional benefits or not ("iROC," 2017).

Development, Molecular Biology, and Physiology of the Prostate

Brian Wesley Simons DVM, PhD, Ashley Evan Ross MD, PhD

The focus of this chapter is on the development, anatomy, histology, and physiology of the prostate and seminal vesicles, the male sex accessory glands that contribute to seminal fluid. A general and molecular knowledge regarding the formation and physiologic function of the prostate is becoming increasingly important because reactivation or recapitulation of developmental processes appears to occur during pathological processes such as benign prostatic hyperplasia (BPH) and the development of aggressive prostate cancer (Marker, 2008; Pritchard et al., 2009; Schaeffer et al., 2008). In addition, the physiologic processing of prostate-specific antigen (PSA) and other cellular constituents of the prostate has begun to play increasingly important roles in the development of clinical prostate biomarkers (Loeb and Catalona, 2014; Mikolajczyk et al., 2004; Vickers et al., 2011).

Developmental and Cell Biology

Prostate

Regional Differentiation of the Lower Urinary Tract

The prostate is a derivative of the primitive endoderm (gut tube). Regional differentiation of the primitive gut tube into foregut, midgut, and hindgut is followed by a swelling at the caudal end that creates the cloaca. The *cloaca*, a Latin term meaning “sewer,” receives output from the urinary and intestinal tracts and represents the fully differentiated state in birds, reptiles, amphibians, marsupials, and monotremes. In placental mammals, however, the cloaca divides during embryogenesis to create separate urogenital and digestive outlets. The ventral urinary compartment is called the *primitive urogenital sinus*, which further segments into the urinary bladder at its cranial end and the urethra at its caudal terminus. Differentiation of the pelvic portion of the urogenital sinus is sexually dimorphic and, in males, forms the prostatic and membranous urethra, prostate, and bulbourethral glands.

Prostate Budding

In males, the prostate develops just caudal to the bladder neck via the proliferation of epithelial buds extending out from the urogenital sinus epithelium. Prostate organogenesis occurs in four overlapping stages. Androgen exposure of the urogenital sinus directly or indirectly initiates the first stage, prostate lineage commitment of regions of the urogenital sinus epithelium. In the second stage, solid cords epithelial cords, or prostate buds, form and invade urogenital sinus mesenchyme at stereotyped locations that pattern the future development of distinct prostate lobes in the rodent and, potentially, zones in the human. These regions prepare for epithelial bud invasion by “mesenchymal condensation,” a process in which urogenital sinus mesenchymal cells (cells constituting loose connective tissue that will differentiate into stromal elements) become closely packed together (Thomson, 2008). This condensation occurs in males and females and is therefore androgen *independent*. In contrast, epithelial budding is strictly androgen *dependent* and represents the first events in prostate development that are identifiable at the light microscopic level. Prostate budding requires intricate epithelial-mesenchymal interactions (Fig. 143.1). In humans, prostate budding occurs during the 10th week of gestation. In mice, prostate budding occurs on the 17th day of gestation, 2 days before birth. Androgen exposure is not only *necessary* but also *sufficient* to drive prostatic differentiation and growth in the embryo. This fact, along with the ability to easily manipulate androgen levels in experimental animals, makes the prostate a particularly appealing subject for the study of epithelial cell fate determination (Cunha et al., 1987; Schaeffer et al., 2008). In the third stage of prostate organogenesis, prostate buds elongate and branch to form the mature prostate network, (postnatal days 1 to 14 in mice) as part of a sophisticated branching morphogenesis program (Sugimura et al., 1986). Finally, the ducts canalize, and cytodifferentiation of the epithelium results in mature prostate glands.

FIG. 143.1 Stromal-epithelial interactions. Shown is a schematic of the types of stromal-epithelial interactions in information transfer and regulation within the prostate. Testosterone and growth factors interact on and between stromal and epithelial cells. The production of growth factors is either stimulated or inhibited by androgens. The growth factors can function on the same cell (autocrine) or on distant cells (paracrine). Nitric oxide (NO) is formed from nerve cells, endothelial cells, or macrophages and affects smooth muscle contraction (see text for details). Important features in this schematic are (1) three types of prostate epithelial cells—neuroendocrine, secretory, and basal; (2) five important prostatic stromal

cells—smooth muscle, fibroblast, immune cells, endothelial cells, and nerve cells; (3) testosterone converted to dihydrotestosterone (DHT) by 5α-reductase in the stromal compartment; (4) three sources of NO production in the prostate—nerve, immune cells (e.g., macrophages), and endothelial cells; and (5) stromal-epithelial interactions mediated through various growth factors (see text). *BFGF,* Basic fibroblast growth factor; *ECM,* extracellular matrix; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *IGF,* insulin-like growth factor; *IGFBP,* insulin-like growth factor binding protein; *KGF,* keratinocyte growth factor; *PSA,* prostate-specific antigen; *T,* testosterone; *TGF,* transforming growth factor; *TSH,* thyroid-stimulating hormone.

Cytodifferentiation

Prostate epithelium begins as a homogeneous cell compartment that differentiates (after birth in mice) into distinct basal (adjacent to stroma) and luminal cell types (Wang et al., 2001). Some epithelial cells co-express basal and luminal markers and are called *intermediate cells*. A fourth cell type, the neuroendocrine cell, is present in large numbers before prostate epithelial budding and decreases during embryonic development (Aumuller et al., 2001).

Molecular Features of Prostate Development

Induction of Prostate Budding.

High levels of circulating testosterone in male embryos initiate prostate development. Testosterone is converted to dihydrotestosterone (DHT) in the UGS by 5α-reductase (Berman et al., 1995), which binds to and activates androgen receptor (AR). Exposure to sufficient levels of testosterone at key developmental time points initiates prostate development regardless of genetic sex, suggesting a primary role for androgens in prostate induction. Recombination experiments in mice have shown that prostate lineage commitment and induction of epithelial budding require paracrine signaling from urogenital sinus mesenchyme (UGM) to adjacent urogenital sinus epithelium (UGE), and that intact AR signaling is required in UGM but not UGE for prostate induction (Cunha and Lung, 1978). Thus the action of androgens appears to be indirect, leading to the hypothesis that mesenchymal cells secrete inductive factors in response to androgens called *andromedins* (Tenniswood, 1986; Yan et al., 1992). Although AR signaling is the primary motivating force behind prostate development, it specifies only the timing of events, not their location. The AR signaling machinery is present diffusely throughout the lower genitourinary tract (Berman et al., 1995; Takeda et al., 1985). Prostate epithelial buds form at precise locations through mechanisms that are not understood.

Two main hypotheses have been proposed to describe the mechanism of induction of prostate budding by UGM, the andromedin model and the smooth muscle model (Toivanen and Shen, 2017). In the andromedin model, AR signaling in UGM induces focal expression of signaling factors (andromedins) that induces prostate budding at that spot. The alternative smooth muscle model hypothesizes that andromedin expression is constitutive throughout the UGS, but maturation of smooth muscle between the mesenchyme and epithelium forms a barrier that prevents signal transduction. In this model, AR signaling in the mesenchyme indirectly induces prostate budding by preventing smooth muscle maturation and allowing inductive signals to reach the UGE. Spatial control of bud induction may involve paralogous homeobox *(Hox)* genes, which are transcriptional regulators that govern differential gene expression along the craniocaudal (head to tail) and proximodistal (e.g., shoulder to fingertip) axes in a variety of tissues, including the genitourinary tract (Beck et al., 2000; Kmita and Duboule, 2003). In vertebrates, the paralogous *Hox* genes exist as four similar clusters (clusters A, B, C, and D), each of which resides on a separate chromosome and encodes genes whose chromosomal position from 3′ to 5′ mirrors their expression pattern in the embryo. The paralogous genes are distinct from other, more distantly related transcription factor families that also contain DNA-binding homeobox motifs, such as the NK family, whose members are expressed in a more discrete, organ-specific manner (e.g., see the discussion of Nkx3.1, later). Paralogous *Hox* genes are sequentially numbered from 1 to 13, with the higher numbers in the 5′ position showing the most distal or caudal expression patterns. Accordingly, *Hoxa13, Hoxb13,* and *Hoxd13* are *paralogs* on chromosomes 7, 17, and 2, respectively, and have overlapping expression patterns and functions in distal genitourinary tract development. *Hoxb13* regulatory elements have been characterized that restrict its function to the caudal end of the genitourinary and digestive tracts and can be used to engineer androgen-independent prostatic expression of genes of interest (McMullin et al., 2009). Homozygous mutations in individual *Hox* genes result in subtle changes in prostatic branching patterns (Podlasek et al., 1997) and/or defective epithelial maturation (Economides and Capecchi, 2003). Mutations involving more than one of these genes results in significantly more severe urogenital phenotypes, such as significant prostate hypoplasia in *Hoxd13/Hoxb13* compound mutant mice or failure of separate urinary and gastrointestinal tract outlets to form in *Hoxa13/Hoxd13* compound mutants (Kondo et al., 1997; Warot et al., 1997).

Mesenchymal condensation occurs in males and females, so it is not sufficient to drive prostate development but may be necessary. Condensation of the ventral mesenchymal pad is defective in mice lacking the gene for Noggin (see the section on the transforming growth factor-β [TGF-β] family, later, for further discussion of the roles of Noggin in prostate development), which antagonizes binding of bone morphogenetic protein (BMP) ligands to their receptors (Cook et al., 2007). This observation suggests that BMP signaling enhances mesenchymal condensation, either by direct action on mesenchyme or through regulation of epithelial-derived factors important in this process. Condensed mesenchyme is highly enriched for expression of fibroblast growth factors (FGFs) that are essential for epithelial bud outgrowth. For example, mice with engineered mutations of the mesenchyme-specific growth factor *Fgf10* gene generate small abortive epithelial buds and fail to grow prostates (Donjacour et al., 2003).

Epithelial Budding.

The earliest event seen in the epithelium during prostate development appears to be the upregulation of sex-determining region Y–box 9 (Sox9), an androgen-dependent transcription factor, induced via mesenchymal-dependent FGF signaling (Huang et al., 2012). Sox9 appears to be crucial for the initiation of prostate epithelial lineage. After this, there is increased epithelial expression of the NK homeobox transcription family member Nkx3.1. This transcription factor influences the degree of branching in the mature mouse prostate, where it can also act as a tumor suppressor (Abate-Shen et al., 2008; Bhatia-Gaur et al., 1999; Bieberich et al., 1996).

Mutations in the transcriptional regulator p63 *(TP63)* (Signoretti et al., 2000) or in the AR signaling axis (Cunha et al., 1987) can also abolish prostate induction. TP63 has transcriptional repressor and activator activities that balance differentiation and stem and progenitor cell functions in epithelia (McKeon, 2004). The transcriptional targets of TP63 in prostate epithelial cells (PrECs) remain to be elucidated (Grisanzio and Signoretti, 2008).

Noggin mutations selectively impair budding of the ventral lobes of the prostate, leaving anterior and dorsolateral budding unimpaired (Cook et al., 2007). Overall, however, the process appears to be a very robust one, with evidence of prostate epithelial bud formation persisting in the presence of a variety of genetic mutations that affect future steps in prostate ductal morphogenesis, particularly branching morphogenesis.

Once set in motion, prostate growth and homeostasis continue to require androgens throughout life. This requirement appears to continue to be indirect, through mesenchymal or stromal AR signaling. Epithelial branching morphogenesis occurs through signaling cascades that inhibit further outgrowth along the long axis of an extending epithelial bud while stimulating lateral growth at its tip (Hogan, 1999). Through engineered deletion of genes in transgenic mice, several individual genes and components of classic morphogenetic pathways have been shown to be required for branching morphogenesis. Indeed, morphologic aberrations seen on interruption of a cellular pathway may be the most sensitive measure of a role for that pathway in regulation of prostate growth. Accordingly, a wide variety of genes and pathways have been strongly implicated in prostate branching morphogenesis, only a few of which are covered here. For a more comprehensive perspective, including additional pathways such as those centered around Notch and Forkhead proteins, the reader is referred to recent reviews (Leong and Gao, 2008; Matusik et al., 2008).

Nkx3.1 and Sox9.

Nkx3.1 helps determine the branching pattern of the prostate, as demonstrated by the reduced numbers of duct tips seen in mice with engineered *Nkx3.1* deletion (Bhatia-Gaur et al., 1999). This relatively subtle phenotypic change may be important, however, as indicated by a dramatic decrease in the ability of Nkx3.1-mutant prostates to manufacture mature secretory proteins (Bhatia-Gaur et al., 1999). In addition to its role in the initiation of prostate development, Sox9 appears required for bud growth and branching as well as ductal outgrowth (Thomsen et al., 2008).

Fibroblast Growth Factors.

The FGF family of related secreted peptides promotes growth in recipient cells by binding to cell surface receptors and activating intracellular second-messenger cascades. Epithelial branching morphogenesis, be it in the lung, salivary gland, mammary gland, or prostate, requires such signals to proceed. Of the FGFs, Fgf-7 (keratinocyte growth factor) and Fgf-10 have been studied most extensively in prostate development. Both of these ligands preferentially bind to Fgfr-2 over the three other family members (Fgfr-1, Fgfr-3, and Fgfr-4)

(Thomson, 2001, 2008). Ligand binding activates the intracellular microtubule-associated protein kinase (MAPK) pathway, leading to enhanced activity of growth-promoting transcription factors and increased proliferation.

Fgfr-2 is expressed on developing PrECs, where it can interact with its coreceptor Frs-2α. Fgf-7 and Fgf-10, in contrast, are secreted by prostate mesenchyme. This arrangement, along with androgen-independent growth of prostate organ cultures exposed to these ligands, has led to the proposal that they act as andromedins (Lu et al., 1999; Yan et al., 1992). Accordingly, Fgf-10–deficient mice have almost complete failure of prostate development, and mice lacking Fgfr-2 or Frs-2α demonstrate prostate hypoplasia and decreased epithelial branching (Donjacour et al., 2003).

Wnt Signaling Pathway.

In a variety of organs, Wnt signaling regulates proliferation and differentiation during development. A similar role is seen in prostate development, in which multiple Wnt ligands are expressed during prostate budding (Mehta et al., 2011; Zhang et al., 2006), and canonical Wnt targets such as Lef1 and Axin2 are upregulated in prostate bud epithelium (Kruithof-de Julio et al., 2013; Simons et al., 2012). Deletion of β-catenin, a critical component of canonical Wnt signaling, during prostate development inhibits prostate differentiation and budding (Francis et al., 2013; Mehta et al., 2013; Simons et al., 2012).

Hedgehog Signaling Pathway.

Across a variety of organs, elaboration of secreted hedgehog (Hh) ligands (Sonic hedgehog, Indian hedgehog, and Desert hedgehog) by epithelial cells and reception in adjacent mesenchyme coordinate the activities of the Gli family proteins in regulating hedgehog pathway target genes. In the mesenchyme of developing prostate, several Hh target genes have been identified (Yu et al., 2009), including the cytokine *Cxcl14*, the insulin-like growth factor–binding protein *Igfbp3*, and the delta/notchlike epidermal growth factor–related receptor *Dner*. The roles of these particular genes in prostate development have yet to be ascertained, but, as a whole, Hh pathway target genes have been implicated in placement of prostate epithelial buds and in subsequent ductal branching and outgrowth. In particular, buds form in the absence of the dominant Hh ligand in the prostate (Berman et al., 2004) but are mislocalized in prostates of mice bearing mutations of downstream effectors of the pathway, Gli proteins (Doles et al., 2006). Later in development, Hh ligands enhance epithelial outgrowth and branching (Freestone et al., 2003), which proceed abnormally in prostate organ cultures treated with Hh pathway antagonists (Berman et al., 2004; Freestone et al., 2003; Lamm et al., 2002). In adult animals the pathway may play a role in homeostasis, as indicated in a failure of prostates to regenerate after castration of animals treated with antibodies or small molecules that block Hh signaling (Berman et al., 2004). Taken together, these data indicate a growth-promoting role for the pathway in prostate epithelium, one that may have clinical relevance in pathologic prostate growth (Shaw and Bushman, 2007).

Transforming Growth Factor-β Superfamily.

TGF-β superfamily members include TGF-β, as well as growth and differentiation factors (GDFs) and BMPs. These factors act through transmembrane receptors and the SMAD family of intracellular signal transducing proteins (Schmierer and Hill, 2007). Little is known about GDFs in the prostate, but TGFs and BMPs are likely to play important roles. In organogenesis this superfamily is best known as a mesenchymal mediator of epithelial growth suppression, but (less frequently) they can also stimulate growth and/or be produced by epithelial cells. TGF-β1 inhibits net growth of the prostate but can stimulate growth in certain regions of the gland, particularly in the distal tips of the ventral prostate (Tomlinson et al., 2004a). Although the mechanism for growth promotion by TGF-β1 is unclear, the growth suppressive effect could reasonably relate to its ability to suppress levels of another mesenchymal growth factor, FGF-10 (Tomlinson et al., 2004b) (see FGF section, earlier). A similar mechanism could remain in place in mature males, in whom TGF-β signaling in proximal ducts is believed to help to maintain prostate epithelial stem cells in a quiescent (growth-suppressed) state (Salm et al., 2005). BMP-4 and BMP-7 exert important and highly localized growth-suppressive activities in prostate development that help guide branching morphogenesis and prevent overproduction and disorganized epithelial growth. Like TGF-β, BMPs are most active during epithelial budding and subsequent prostate branching (Grishina et al., 2005; Lamm et al., 2001; Tomlinson et al., 2004a) (embryonic day 17 through postnatal day 5 in the mouse). Activation of BMP signaling suppresses branching morphogenesis, as indicated by experimental addition of exogenous BMP-4 or BMP-7 protein to prostate organ cultures (Grishina et al., 2005; Lamm et al., 2002) or by genetic deletion of the BMP inhibitor Noggin (Cook et al., 2007). BMP inactivation can show the opposite effect, as epithelial overgrowth of prostates with genetic deletion of BMP-7 (Grishina et al., 2005).

Prostate Zonal and Lobar Anatomy.

The rodent prostate is divided into paired anterior, dorsolateral, and ventral lobes. Each empties into the urethra separately at its proximal extreme, with the distal end floating freely in the pelvic cavity. In contrast, the human prostate, like that of most primates and canine species, grows as a single organ encircling the urethra. The individual prostate zones, however, have distinct architectural and molecular features and have a propensity to develop distinct pathologies (Table 143.1). For instance, the transitional zone surrounding the urethra has the propensity to undergo BPH, making males vulnerable to urinary obstruction, whereas the peripheral zone, which contains the majority of the glandular elements of the prostate, is the most common site for prostate cancer. In rodents, the anterior, ventral, and dorsolateral lobes are named for the distinct locations of the urethra from which they originate. Each lobe also has a different branching pattern with a distinctive histologic appearance. These differences, reviewed by Timms (2008), have been likened to different zones of the human prostate histologically (Price, 1963), molecularly (Berquin et al., 2005; Thielen et al., 2007), and in terms of propensity to be affected by disease (the dorsolateral prostate, for instance, is most similar to the human peripheral zone). In mice, mRNA transcripts for spermine-binding protein, probasin, and renin-1 are specific for ventral, dorsolateral, and anterior lobes, respectively (Cook et al., 2007), whereas human zone-specific gene expression has not been as well characterized.

TABLE 143.1

Summary of the Anatomy and Cell Biology of the Prostate Gland

COMPONENTS	PROPERTIES
DEVELOPMENT	
Seminal vesicles	From wolffian ducts through testosterone stimulation
Prostate	From urogenital sinus through dihydrotestosterone stimulation
PROSTATE ZONES	
Anterior fibromuscular	30% of prostate mass, no glandular elements, smooth muscle
Peripheral	Largest zone, 75% of prostate glandular elements, site of carcinomas
Central	25% of prostate glandular elements; surrounds ejaculatory ducts
Transitional	Smallest zone, surrounds upper urethra complex, sphincter
	5% of prostate glandular elements, site of benign prostatic

	hyperplasia
	15%–30% of prostate volume
EPITHELIAL CELLS	
Basal	Small and flattened undifferentiated, nonsecretory cells with a low proliferative index (<1%) that express keratins 5, 14, and 18
Intermediate	Proliferating cell type that has characteristics intermediate between basal and secretory cells, including production of basal and secretory cell keratins
Columnar secretory	Terminally differentiated, nondividing, rich in acid phosphatase and prostate-specific antigen; 20 μm tall, most abundant cell, keratins 5 and 18
Neuroendocrine	Terminally differentiated, nonproliferating cells that express serotonin, chromogranin-A, neuron-specific enolase, and synaptophysin proteins
STROMAL CELLS	
Smooth muscle	Rich in α-actin, myosin, and desmin
Fibroblast	Vimentin rich and associated with fibronectin
Endothelial	Associated with fibronectin; alkaline phosphatase positive
TISSUE MATRIX	
Extracellular matrix	
Basement membrane	Type IV and V collagen meshwork that is laminin rich and supports basal cells, stem cells, transit-amplifying cells, and secretory epithelium
Connective tissue	Type I and type III fibrillar collagen; elastin
Glycosaminoglycans	Sulfates of dermatan, chondroitin, and heparin; hyaluronic acid
Cytomatrix	Tubulin, α-actin, and intermediate filaments of keratin
Nuclear matrix	Dynamic structure of the nucleus that directs the functional organization of DNA into loop domains; contains ribonuclear proteins

Although the gene expression patterns of individual human prostate zones have not been extensively studied, there have been efforts to characterize the zonal distribution of prostate-secreted proteins, in particular of PSA, at least in the adult prostate. For instance, Mikolajczyk et al. (2000a) described BPSA (BPH-related PSA) as a form of unbound PSA that is increased in the transition zone of the prostate. In contrast, the proPSA zymogen (a precursor of PSA) has been found to be preferentially detected in the peripheral zone (Mikolajczyk et al., 2000b).

Key Points: Embryonic Development

- The wolffian ducts develop into the seminal vesicles, epididymis, vas deferens, ampulla, and ejaculatory duct. The developmental growth of this group of glands is stimulated by fetal testosterone and not DHT.
- Through tissue recombination experiments in mice and rats, the developing urogenital sinus mesenchyme and epithelium have been shown to partner in prostate development. That is, the development, growth, and function of the male and female urogenital tract require stromal-epithelial interaction and action of steroid sex hormones. Androgen acts on the mesenchyme to indirectly induce prostate epithelial outgrowth during development and homeostasis in adulthood.

Prostate Cell Types

The prostatic epithelium in the human is composed of two major cellular compartments: epithelial cells and stromal cells (see Table 143.1). The prostate epithelial compartment consists of basal epithelial cells, intermediate cells, neuroendocrine cells, and luminal secretory epithelial cells (De Marzo et al., 1998a). The stromal compartment architecturally serves as structural support and consists predominantly of connective tissue, smooth muscle cells, and fibroblasts. Most prostate cell types have been characterized in vitro (Peehl, 2005).

In most glands with renewing cell populations, there is a steady-state flow of cells from mostly quiescent stem cells to a more rapidly dividing pool of transient proliferating cells. This proliferating population finally reaches terminal differentiation, characterized by metabolically active secretory epithelium. In the prostate, precise cell lineage remains uncertain. Although precise cell lineage analysis is possible in mice, it is unclear if these findings directly translate to human cells. In addition, cytodifferentiation in the embryo during organogenesis may not be maintained by the same cell populations in the adult prostate at homeostasis. Some cells, such as neuroendocrine cells, can be formed from transdifferentiation or by influx of neural crest-derived cells. A hypothetical differentiation scheme for prostate epithelium is presented in Fig. 143.2. As in most multilayered epithelia, stem cells reside in the basal compartment and can give rise to all of the other epithelial cell types, as well as neuroendocrine cells. These include fully differentiated secretory cells that line glandular lumens (luminal cells), neuroendocrine cells that secrete bioactive peptides, and intermediate cells that show phenotypic features that are intermediate between basal cells and luminal cells.

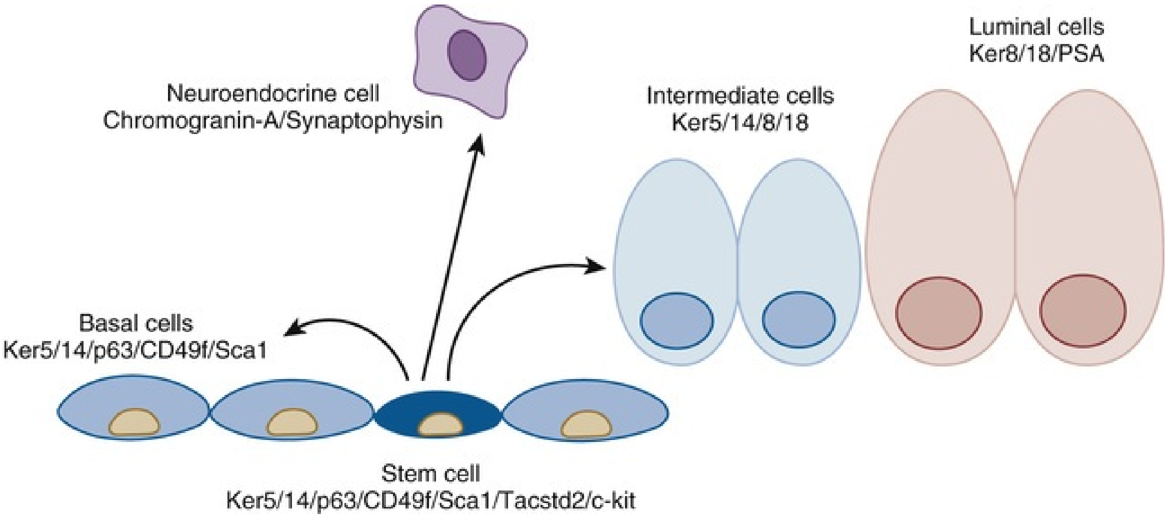

FIG. 143.2 Hypothetical cell differentiation in adult prostate. Basal cells *(medium blue)* express basal cell proteins, including cytokeratin (CK) proteins 5 and 14, p63, CD49f, and Sca1. Stem cells within the basal cell compartment *(dark blue)* express basal cell proteins, as well as Tacstd2 and c-kit. Basal stem cells populate the basal cell compartment *(medium blue)* and eventually intermediate cells *(light blue).* Intermediate cells proliferate and differentiate into quiescent luminal cells *(orange).* Neuroendocrine cells *(purple)* are also believed to derive from epithelial stem cells. Formal lineage tracing has not been performed in all of these cell types; thus the true differentiation pathway remains to be determined. (Modified from Wang Y, Hayward S, Cao M, et al.: Cell differentiation lineage in the prostate. *Differentiation* 68[4–5]:270–279, 2001.)

Luminal Epithelial Cells.

The luminal epithelial cell is the “workhorse” of the prostate gland, responsible for epithelial barrier integrity and production of prostatic secretion. Luminal cells constitute most of the prostate epithelium. These tall (10 to 20 µm) columnar secretory epithelial cells are terminally differentiated and have a low proliferative index (De Marzo et al., 1998a); they are easily distinguished by their morphologic features and abundant secretory granules and enzymes. Secretory cells produce a variety of proteins that characterize prostatic differentiation, including PSA, acid phosphatase, AR, leucine amino peptidase, and 15-lipoxygenase-2 (Bhatia et al., 2003; Shappell et al., 1999). They are also rich in keratin filaments (subtypes 8 and 18) (van Leenders and Schalken, 2003). Secretory cells appear in rows like a picket fence with each cell connected to the next by cell adhesion molecules (CAMs); the apical aspect of these cells projects into the lumen, with the base attached to a basement membrane through integrin receptors (Knox et al., 1994). The nucleus is at the base just below a clear zone (2 to 8 µm) of abundant Golgi apparatus, and the upper cellular periphery is rich in secretory granules and enzymes. The apical plasma membrane facing the lumen possesses microvilli, and secretions move into the open collecting spaces of the acinus. These epithelial cells ring the periphery of the acinus and produce secretions into the acini that drain into ducts connected to the urethra.

Basal Cells.

Basal cells (De Marzo et al., 1998a) are the smallest of epithelial cells. Basal cells express a distinct keratin subtype profile (subtypes 5 and 14) compared with the columnar luminal epithelial cells (subtypes 8 and 18). These cells are typically pyramid shaped with relatively little cytoplasm and condensed chromatin. Basal cells rest on the basement membrane wedged between the bases of adjacent, tall, columnar epithelial cells. The basal cell compartment expresses little or no androgen receptor and is almost devoid of secretory products, such as PSA and prostatic acid phosphatase (PAP) (see Fig. 143.2). Indeed, when mice are castrated after implantation with human prostate primary xenografts and then restimulated with testosterone, the basal cell population is highly overrepresented, consistent with the concept that the human basal compartment also contains prostate epithelial stem cells (Huss et al., 2004).

Prostate Epithelial Stem Cells.

In most glands with renewing cell populations, there is a steady-state flow of cells from mostly quiescent stem cells to a more rapidly dividing pool of transient proliferating cells. This proliferating population finally reaches terminal differentiation, characterized by metabolically active secretory epithelium. In the human prostate, cell lineage has not been rigorously determined but has been inferred from a variety of sources. A hypothetical differentiation scheme for prostate epithelium is presented in Fig. 143.2. In this model, stem cells reside in the basal compartment and appear to give rise to all of the other epithelial cell types, as well as neuroendocrine cells. These include fully differentiated secretory cells that line glandular lumens (luminal cells), neuroendocrine cells that secrete bioactive peptides, and intermediate cells that show phenotypic features that are intermediate between basal cells and luminal cells. Lineage tracing experiments in human prostate suggest bipotential basal stem cells are located at the proximal portion of ducts and can generate the complete spectrum of cell types, whereas human luminal progenitor cells are unipotent and only generate luminal cells (Moad et al., 2017). Studies in mice suggest mouse prostate stem cells follow a different model. In the adult mouse prostate, stem cells are present in luminal and basal compartments and retain the ability to regenerate the full spectrum of cell phenotypes from either compartment (Wang et al., 2009).

These experiments used lineage tracing and in vivo grafting assays to demonstrate critical stem cell characteristics, including the ability of long-lived cells to proliferate indefinitely and to give rise to more differentiated phenotypes. Tsujimura et al. (2002) demonstrated DNA label-retaining PrECs with long-term proliferative potential that were preferentially localized to the proximal segments of prostatic ducts of adult mice. Studies to determine the expression profile that identifies prostate stem cells has found multiple possible candidates including the mouse stem cell antigen Sca1, the basal cell integrin α_6 (Itga6 or CD49f), the tumor-associated calcium signal transducer Tacstd2 (also known as *Trop2*), and the stem cell factor receptor c-kit (Burger et al., 2005; Goldstein et al., 2008; Lawson et al., 2007; Leong and Gao, 2008; Xin et al., 2005). Studies in human prostate cells have additionally identified CD133 and DLK1 as potential stem cell markers (Moad et al., 2017; Vander Griend et al., 2008). Further study of prostate cell differentiation is required to uncover the potential and lineage of prostate cell types and to determine if mouse and human prostate differentiation are similar.

Intermediate Cells.

Intermediate cells are so named because they possess phenotypic characteristics intermediate between basal and luminal cells. Similarities of these cells to prostate cancer cells have marked them as hypothetical substrates for neoplastic transformation (De Marzo et al., 1998b; Verhagen et al., 1992), although their susceptibility to carcinogenesis is unknown. These investigators proposed that intermediate cells fulfill a transient amplifying function, providing a short-term amplification function for the long-term proliferative capabilities of basal stem cells. Intermediate cells produce basal cell keratins (5 and 14) and the secretory cell keratins 8 and 18 (De Marzo et al., 1998b; Schalken and van Leenders, 2003). Uzgare et al. (2004) reported transient amplifying properties of human intermediate cells in culture: a high proliferative fraction with the ability to proliferate for a limited number of generations. Survival of terminally differentiated secretory luminal cells and proliferation of intermediate cells require androgens potentially acting indirectly through the secretion of androgen-regulated growth factors by the stromal compartment (andromedins) (Uzgare et al., 2004).

Neuroendocrine Cells.

Neuroendocrine cells are cells that release hormones in response to neural stimulation. In the prostate, neuroendocrine cells reside among the more abundant secretory epithelial cells in the normal prostate gland as well as in the urothelium of the prostatic urethra (Aumuller et al., 2001). There are two types of neuroendocrine cells: the first is open and possesses specialized microvilli that protrude into the lumen; the second is closed with long dendrite-like processes that extend to nearby epithelial cells and basal cells close to afferent and efferent nerves (Abrahamsson, 1999; diSant-Agnese and deMesy-Jensen, 1984; diSant-Agnese et al., 1985; Vashchenko and Abrahamsson, 2005).

The development of this cell type during prostate organogenesis has not been well characterized, and the source of these cells has been variously proposed to be neural crest or urogenital sinus endoderm (Aumuller et al., 2001; Goldstein et al., 2008). Aumuller et al. (2001) demonstrated that neuroendocrine cells are readily identified in male and female urogenital sinus epithelium before human prostate development, suggesting that these may represent a separate lineage that is independent of prostate epithelium. More recently, Goldstein et al. (2008) showed that neuroendocrine, basal, and secretory luminal cells can originate from a common pluripotent Trop2-expressing prostate epithelial stem cell precursor. Recent lineage tracing studies suggest the majority of neuroendocrine cells in mice and humans are neural crest derived, but the factors that initiate neuroendocrine transdifferentiation of epithelial cells or migration of neural crest cells remain undefined (Szczyrba et al., 2017).

Current evidence suggests that neuroendocrine cells can influence growth, differentiation, and secretory activity of the prostate epithelium through paracrine and autocrine mechanisms (Abrahamsson, 1999; Vashchenko and Abrahamsson, 2005). Neuroendocrine cells bring about their regulatory activity by the secretion of hormonal polypeptides or biogenic amines such as serotonin. High-pressure liquid chromatography measurements have shown that normal human prostatic tissue contains approximately 1400 ng of serotonin per gram of tissue, and this would certainly emphasize the importance of these cells (Davis, 1987). Higgins and Gosling (1989) have studied the structure and intrinsic innervations of the normal human prostate and have observed acetylcholinesterase-containing nerves associated with smooth muscle in the peripheral and the central parts of the prostate. In addition, they have shown that the majority of the acini in the peripheral and central regions possess a rich plexus of autonomic nerves and that vasoactive intestinal peptide-positive nerve fibers are found in relation to the epithelial lining acini in the central and peripheral regions of the gland. Lepor and Kuhar (1984) characterized and studied the location of the muscarinic cholinergic receptor in human prostatic tissue and localized it to the epithelial cells. This is consistent with the neuropharmacology of muscarinic cholinergic agonist, which has a marked effect on increasing prostatic secretion. However, the α_1-adrenergic receptor has its effect in the human prostatic stromal compartment. This is of clinical importance because of the use of selective α_1-adrenergic antagonists to alleviate bladder outlet obstruction secondary to BPH (Lepor, 1993). Recent work has demonstrated three subtypes of the α_1-adrenergic receptor (α_{1A}, α_{1B}, and α_{1D}). Of these, the α_{1A} receptor appears to be linked to smooth muscle contraction of the prostate (Lepor et al., 1993).

Neuroendocrine cells are terminally differentiated (i.e., nonproliferating) and do not express detectable AR, PSA, or Bcl-2. These cells release peptide hormones or prohormones by fusion of intracellular granules with the cell membrane and exocytosis of their contents. In addition to serotonin, neuroendocrine cells produce numerous bioactive macromolecules (major examples include bombesin, neuron-specific enolase, calcitonin gene family members, thyroid-stimulating hormone–like peptide, somatostatin, synaptophysin, and parathyroid hormone–like peptide). Neuroendocrine factors appear likely to influence the growth, differentiation, and secretion of epithelium of the prostate in normal and malignant conditions (Vashchenko and Abrahamsson, 2005).

Key Points: Prostate Epithelial Cell Types

- The prostatic epithelium in the human is composed of two major cell compartments: epithelial cells and stromal cells.

- The epithelial cell types include mature secretory and terminally differentiated cells, neuroendocrine cells, intermediate cells, and basal cells.
- Prostatic stem cells reside in the basal compartment and are enriched in the proximal portions of prostatic ducts.

Stroma and Tissue Matrix

The noncellular stroma and connective tissue of the prostate make up what is termed the *ground substance* and the *extracellular matrix* in what was first suggested by Arcadi (1954) to play an important role in prostate function and disease. The extracellular matrix has long been recognized as one of the important inductive components during normal development of many different types of cells (Cunha, 1976; Bissell et al., 1982; Getzenberg et al., 1990; Hay, 1981; Risbridger et al., 2005). Classic tissue recombination experiments by Cunha et al. (1987) have clearly shown the direct importance of the isolated embryonic mesenchyme to the induction of differentiation of normal prostatic epithelial cells (see earlier discussion).

The epithelial cells rest on the basement lamina or membrane, which is a complex structure containing, in part, collagen types IV and V, glycosaminoglycans, complex polysaccharides, and glycolipids. This layer forms an interface to the stromal compartment that provides structural support for the basal cells and their progeny. It consists of an extracellular matrix, ground substance, and a variety of stromal cells, including the fibroblasts, capillary and lymphatic endothelial cells, smooth muscle cells, neuroendocrine cells, and axons (Taylor and Risbridger, 2008).

The **cytomatrix** (cytoplasmic skeleton) terminates in the center of the cell by direct attachment to the **nuclear matrix.** The prostatic epithelial cell therefore has direct structural linkage via the matrix system from the DNA to the plasma membrane. The cytomatrix then makes direct contact with the basement membrane, extracellular matrix, and ground substance of the stroma. This entire interlocking tissue scaffolding or superstructure is termed the ***tissue matrix*** and may have dynamic properties in ordering and controlling biologic processes as well as in the transport of secretions from the sex accessory tissues (Etienne-Manneville, 2004; Getzenberg et al., 1990; Hallmann et al., 2005; Konety and Getzenberg, 1999; Miner and Yurchenco, 2004).

Understanding the biologic components of the tissue matrix system within sex accessory tissues is paramount to understanding its physiology. The laminin proteins are glycoproteins of the extracellular matrix that mediate attachment of cells to the type IV collagen of the basement membrane (Hallmann et al., 2005; Miner and Yurchenco, 2004; Yurchenco et al., 2004). Laminin is produced by epithelial cells but not by fibroblasts; it is a large molecule (approximately 800 kD) with molecular domains that interact with the type IV collagen of the basement membrane and with integrin-type receptors within the cell surface glycocalyx of the epithelial cell (Aumailley et al., 2005). Laminins are the major anchor filaments in the basement membranes of epithelial cells that stabilize attachment of hemidesmosomes via $\alpha_6\beta_4$ integrin (Brar et al., 2003; Miner and Yurchenco, 2004). **The key functional properties of the laminins are cell adhesion, proliferation, differentiation, growth, and migration.** Laminin surrounds the basement membrane of prostate acinar epithelial cells, capillaries, smooth muscle, and nerve fibers but not lymphatics, lymphocytes, or fibroblasts; the laminin structure and its distribution are disrupted in BPH and higher-grade prostatic interepithelial neoplasia and higher-grade prostate neoplasms (Brar et al., 2003; Miner and Yurchenco, 2004; Sinha et al., 1989).

In summary, the development and maintenance of the prostate occur through androgen-dependent and highly regulated tissue morphogenesis in processes involving epithelial cell differentiation, proliferation, and apoptosis (Cunha et al., 2004)**. Communication through numerous extracellular interactions is directed to the intracellular cytoskeleton and then to the nuclear matrix, which ultimately regulates a variety of transcriptional cell functions that control such critical phenotypic qualities as cell size and shape, cell motility, epithelial cell turnover, proliferation, and differentiation** (Getzenberg et al., 1990; Miner and Yurchenco, 2004; Pienta et al., 1993).

Seminal Vesicles and Their Development

The sex accessory tissues include the epididymis, ampullae, seminal vesicles, prostate, Cowper (bulbourethral) gland, and glands of Littre (urethral or periurethral glands). All of these glands have reproductive roles, but the seminal vesicles work in tandem with the prostate and provide an important counterpoint to its biology and pathologic processes. The seminal vesicles are two saccular glands that pair with the vasa deferentia to form the ejaculatory ducts that empty into the craniodorsal aspects of the prostate. Together with the prostate, the seminal vesicles produce seminal fluid that nurtures, protects, and facilitates sperm transport for mammalian reproduction.

The division of labor between the prostate and seminal vesicles is surprisingly variable among species. At one end of the spectrum is the dog, a species in which seminal vesicles are absent and the prostate must therefore carry out the functions that are divided between the two glands in other species. Most mammals, including humans, rats, and mice, occupy the other end of the spectrum, in which the seminal vesicles produce most of the seminal fluid, with the prostate playing a minor role. In species with both glands, physiologic cooperation between the two glands is also appreciable at the molecular level. For example, the major secretory protein product of the seminal vesicles is semenogelin, a 52-kD protein that acts as a substrate for proteolytic enzymes produced by the prostate, including PSA. Proteolysis of semenogelin yields a variety of peptide byproducts that are believed to serve reproductive and antimicrobial functions in humans (Curry and Atherton, 1990). In mice and rats, seminal vesicle and prostate products cooperate to coagulate the ejaculate into a firm copulatory plug in the vagina during mating. The plug serves as a temporary barrier to further mating by the female, potentially blocking impregnation by competing males.

Seminal vesicles develop from the mesonephric (wolffian) ducts shortly before the onset of prostate development. Seminal vesicle development is strictly dependent on an intact AR signaling pathway, including the ligand testosterone (Wilson et al., 1981). This requirement contrasts to development of the human prostate (see later), which, in addition to an intact AR pathway, requires conversion of testosterone into the more potent 5α-reduced androgen, DHT (Andersson et al., 1991; Mahendroo and Russell, 1999).

Thick smooth muscle layers constitute the muscular stroma of the seminal vesicles, which surrounds a short columnar-to-cuboidal epithelium. The epithelium has distinct basal and luminal layers notable for unusually variable nuclear size and shape, a feature that is also found in prostate cancer (Epstein and Netto, 2007). Another notable feature of the epithelium of the seminal vesicles, the almost invariable appearance of gold intracytoplasmic pigment, is usually absent in prostate cancer and helps to clarify any confusion between the two entities. Seminal vesicle pigment is thought to derive from cellular byproducts of nonviable sperm ingested by the seminal vesicle epithelium (spermatophagy).

The seminal vesicles are extremely resistant to disease. Given their proximity, shared functions, and similar endocrine requirements to the prostate, it is striking that diseases of the seminal vesicles in humans are vanishingly rare.

In contrast, prostate disease, at least in Western cultures, is a nearly universal rite of passage into old age (see subsequent chapters on BPH and prostate cancer). Accordingly, contrasting gene expression between seminal vesicles and the prostate has been used as a strategy to discover the molecular basis of prostate cancer risk (Thompson et al., 2008).

Endocrine Control of Prostate Growth

The prostate, like other sex accessory tissues, is stimulated in its growth, maintenance, and secretory function by the continued presence of certain hormones and growth factors. Foremost among these is testosterone, which is converted within the prostate into the more active androgen DHT. Testosterone is synthesized in the Leydig cells of the testes from pregnenolone by a series of reversible reactions. However, once testosterone is converted by 5α-reductase into DHT or converted by aromatase into estrogens, the process is irreversible: **testosterone can be converted to DHT or estrogens, but estrogens and DHT cannot be converted to testosterone.** Androgens, estrogens, and adrenal steroids are believed to have strong effects on different cells and tissues in the body that can vary with development and age. These vary from embryonic development to puberty and on into adult maintenance and aging. Therefore androgen ablation or androgen treatments have a variety of physiologic effects that merit consideration.

The generalized endocrine physiology of the prostate is depicted in Fig. 143.3. The hypothalamus releases a small 10-residue polypeptide (decapeptide) referred to as *luteinizing hormone–releasing hormone* (LHRH), also called *gonadotropin-releasing hormone* (GnRH). Under the stimulation of LHRH the pituitary releases luteinizing hormone (LH), which is transported to the testes and acts directly on the Leydig cells to stimulate de novo steroid synthesis and release of testosterone, the major serum androgen of the body. Most of the estrogen in the male is derived from peripheral conversion of androgens to estrogens through aromatization. Exogenous estrogens, such as diethylstilbestrol, block androgen action not primarily by direct effects on the prostate but indirectly through blocking pituitary function. The estrogen causes a negative feedback on LH release that reduces the serum signal for testicular testosterone production; therefore estrogen acts as an effective “chemical castration.”

FIG. 143.3 Simplified endocrinology of the prostate. Luteinizing hormone–releasing hormone (LHRH), also known as gonadotropin-releasing hormone (GnRH), stimulates the pituitary to release the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which stimulate the Leydig cells of the testes to synthesize testosterone. Testosterone is the major serum androgen stimulating prostate growth. Peripheral conversion of testosterone by aromatization forms the estrogens in the male. The adrenal gland is under stimulation by adrenocorticotropic hormone (ACTH) and releases the minor androgens, such as androstenedione, which is also converted peripherally to estrogens. Prolactin has also been shown to have a minor effect in stimulating androgen-induced prostate growth. The prostate can produce its own growth factors (autocrine or paracrine) or respond to circulating growth factors.

Recent studies in prostate cancer biology have revealed that prostate cancer cells are capable of de novo androgen synthesis, leading to renewed interest in steroid 17α-hydroxylase/17,20-lyase blockade (e.g., abiraterone), or direct AR antagonism (e.g., enzalutamide). However, it is doubtful that benign prostatic epithelial cells produce intracrine androgens in clinically significant amounts because castration leads to nearly complete involution of the prostate. In addition, the adrenal secretes a weak androgen, androstenedione. However, this also is not a major influence on prostate physiology because castration leads to almost complete involution of the prostate, meaning that insufficient adrenal androgens are present to stimulate any meaningful growth of the normal prostate. Similar to serum testosterone, androstenedione can undergo aromatization to estrone. Overproduction of androstenedione, such as occurs in certain forms of congenital adrenal hyperplasia, may stimulate prostate growth; however, again, the role of normal circulating adrenal androgens in regulating prostate growth is minor. The presence of a nontesticular minor androgen source has led to the concept of total androgen blockade for the treatment of advanced prostate cancer, whereby an LHRH agonist and a nonsteroidal antiandrogen are combined to eliminate testosterone production and block any residual androgen stimulation of the prostate from the adrenal gland. With the realization that prostate cancer cells can produce intracrine androgens and various constitutively active AR splice isoforms, true androgen blockade requires further addition of drugs of the newer class such as abiraterone and enzalutamide.

Androgen Production by the Testes

Because the testes produce the major serum androgen supporting prostate and sex accessory tissue growth, it is important to briefly review this function. In the normal human male the major circulating serum androgen is testosterone, which is almost exclusively (approximately 95%) of testicular origin. **Under normal physiologic conditions the Leydig cells of the testis are the major source of the testicular androgens.** The Leydig cells are stimulated by the gonadotropins (primarily LH) to synthesize testosterone from acetate and cholesterol. The spermatic vein concentration of testosterone is 40 to 50 µg/dL, approximately 75 times more concentrated than the level detected in the peripheral venous serum (Hammond, 1978), which is approximately 600 ng/dL. Other androgens also leave the testes by the spermatic vein; these include androstanediol, androstenedione (3 µg/dL), dehydroepiandrosterone (DHEA) (7 µg/dL), and DHT (0.4 µg/dL). The concentrations of these androgens are much lower in the spermatic vein than the concentration of testosterone, with all being less than 15% of the concentration of testosterone.

The total testosterone that enters the plasma is referred to as the *testosterone blood production rate* and is 6 to 7 mg/day in the human. Although other steroids, such as androstenedione from the adrenals, can be converted by peripheral metabolism to testosterone, they account for less than 5% of the overall production of plasma testosterone. The plasma half-life of testosterone is only 10 to 20 minutes, which means that a man undergoing bilateral simple orchiectomy is functionally castrated within 1 to 2 hours of surgery. Therefore the most rapid method of androgen suppression for the purposes of immediate relief of spinal cord compression from prostate cancer metastasis is surgical castration.

The average testosterone concentration in the plasma of a man is approximately 611 ng/dL ± 186, with a normal range of 300 to 1000, which is equal to 10.4 to 34.7 nmol/L in SI units (Table 143.2). Serum testosterone level is not remarkably related to age between 25 and 70 years, although it does decline gradually to approximately 500 ng/dL after 70 years of age. It is recognized that plasma concentrations of testosterone can vary widely in an individual on any one day and may reflect episodic and diurnal variations in the production rate.

TABLE 143.2

Average Plasma Levels of Sex Steroids in Healthy Human Males

STEROID (COMMON NAME)	PLASMA CONCENTRATION (ng/dL)	RELATIVE MOLARITY	DAILY BLOOD PRODUCTION RATE (mg/day)	RELA ANDI (RAT
Testosterone	611 ± 186	100	6.6 ± 0.5	100
Dihydrotestosterone	56 ± 20	9	0.3 ± 0.06	181
5α-Androstane-3α,17β-diol (3β-androstanediol)	14 ± 4	2	0.2 ± 0.03	126
5α-Androstane-3β,17β-diol (3β-androstanediol)		<2	<0.3	18
Androstanediol	161 ± 52	26	0.21	
Androsterone	54 ± 32	9	0.28	53
Androstenedione	150 ± 54	25	1.4	39
Dehydroepiandrosterone	501 ± 98	81	29	15
Dehydroepiandrosterone sulfate	135,925 ± 48,000	17,619		<1
Progesterone		30	4.5	
17β-Estradiol	2.5 ± 0.08		0.4	0.75
Estrone		4.6	0.8	0.04

VP, Ventral prostate.

Metabolic androgens such as 17-ketosteroids are then secreted into the urine as water-soluble glucuronide or sulfate conjugates. The total 17-ketosteroid level in the urine in adult men is 4 to 25 mg/24 h and is not an accurate index of testosterone production, because other steroids from the adrenals as well as nonandrogenic steroids can be metabolized to 17-ketosteroids. Only small amounts (25 to 160 μg/day) of testosterone enter the urine without metabolism, and this urinary testosterone represents less than 2% of the daily testosterone production.

Although testosterone is the primary plasma androgen inducing growth of the prostate gland and other sex accessory tissues, it appears to function as a prohormone in that the most active form of the androgen in the prostate is not testosterone but rather DHT (Anderson and Liao, 1968; Bruchovsky and Wilson, 1968; Farnsworth and Brown, 1963; Fig. 143.4). The formation of DHT involves the reduction of the double bond in the A ring of testosterone through the enzymatic action of the enzyme 5α-reductase (Fig. 143.5). There are at least two isoforms of this enzyme (type 1 and type 2). Type 2 5α-reductase expression predominates in human accessory sex tissues and is localized to the fibromuscular stromal compartment (Silver et al., 1994). The type 1 isoform predominates in skin, in prostatic epithelia, and to a lesser extent in prostatic fibromuscular stroma. Inhibition of 5α-reductase by finasteride appears to be largely selective for the type 2 isoform (Habib et al., 1997; Iehle et al., 1995); the newer agent dutasteride inhibits type 1 and type 2 5α-reductase. Both drugs appear to exert similar effects in terms of reduction in prostatic volume and serum PSA concentration, suggesting that the type 2 isoform is the only clinically significant isoform present in the prostate. **DHT concentration in the plasma of normal men is low, 56 ± 20 ng/dL, in comparison to testosterone,** with a concentration 11-fold higher at approximately 611 ng/dL (see Table 143.2). In summary, although DHT is a potent androgen (2 to 10 times as potent as testosterone in many bioassay systems), its low plasma concentration and tight binding to plasma proteins diminishes its direct importance as a circulating androgen affecting prostate and seminal vesicle growth. In contrast, DHT is paramount within the prostate, where it is formed from testosterone. **DHT is the major form of androgen found within the prostate gland (5 ng/g tissue wet weight) and is fivefold higher than testosterone.** In the prostate, DHT binds to ARs and activates the receptors to regulate a variety of cellular processes. In summary, DHT becomes the major androgen regulating the cellular events of growth, differentiation, and secondary functions in the prostate.

FIG. 143.5 Overview of the synthesis and metabolism of testosterone in four main body compartments: adrenal synthesis of androstenedione, peripheral conversion of androgens (androstenedione and testosterone) to estrogens, formation of active androgen (dihydrotestosterone [DHT]) within the prostate, and inactivation in the liver of testosterone to three types of 17-ketosteroids.

The normal adult male plasma levels of some important steroids are summarized in Table 143.2. These values are derived as averages from numerous studies. Individual values can fluctuate with age, time of day, medications, stress, hospitalization, and environmental changes. For this reason, serum measurements of testosterone should be done only in the morning (e.g., 8:00 AM), because late afternoon measurements can drop by as much as 25% by diurnal variation alone (Brambilla et al., 2009).

Adrenal Androgens

There is evidence that overproduction of adrenal steroids can stimulate growth of the prostate gland. For example, in humans, abnormal virilism has been observed in immature males with a hyperfunctioning adrenal cortex. In rodents, overstimulation of the adrenals can also induce limited prostate growth even in the absence of testicular androgens. For example, administration of exogenous adrenocorticotropic hormone to castrated animals does significantly increase the growth of sex accessory glands (Tisell, 1970; Tullner, 1963; Walsh and Gittes, 1970). However, the effect of normal levels of adrenal androgens on the prostate in noncastrated humans and adult male rats does not appear to be significant because adrenalectomy has little effect on prostate size, DNA, or morphologic characteristics of the sex accessory tissue (Mobbs et al., 1973; Oesterling et al., 1986). Furthermore, after castration in animals, with the adrenals intact, the prostate finally diminishes to a very small size (90% reduction in total cell mass). Finally, the small involuted ventral prostate in the castrated rat cannot be significantly reduced further by additional adrenalectomy or hypophysectomy (Kyprianou and Isaacs, 1987). In castrated rats, the DHT level in the prostatic tissue is approximately 20% that in normal intact animals. Adrenalectomy lowers the DHT to undetectable levels without further diminution in prostate growth. This indicates that a threshold level of DHT is required in the prostate to stimulate growth and that the castrate level is below this threshold. Another conclusion is that the human prostate does not restore itself after castration, indicating that adrenal androgens are insufficient to compensate for the loss of testicular function. Quantitative morphometry of the human prostate (Oesterling et al., 1986) also confirms that the adrenal gland has little effect on the epithelial cell size of the normal prostate.

The adrenal steroid DHEA and the conjugate dehydroepiandrosterone sulfate (DHEAS) as well as androstenedione are androgens synthesized from acetate and cholesterol (see Fig. 143.5) that are secreted by the normal human adrenal glands. Essentially all of the DHEA in the male plasma is of adrenal cortex origin, and the production rate in males is 10 to 30 mg/day. **Less than 1% of the total testosterone in the plasma is derived from DHEA** (Horton, 1976; MacDonald, 1976). The prostate and seminal vesicles of the rat and the human prostate can slowly hydrolyze DHEAS to free steroids through prostatic sulfatase enzymatic activity, but the degree of conversion is low; hence DHEAS is not a potent androgen.

A second adrenal androgen is androstenedione, and the plasma concentration in adult men is approximately 150 ± 54 ng/dL (see Table 143.2). The blood production rate of androstenedione in human males is 2 to 6 mg/day, with approximately 20% of the androstenedione being generated by peripheral metabolism of other steroids. **Androstenedione cannot be converted directly to DHT.** An important role for androstenedione in the male may be its peripheral conversion to estrogens through the aromatase reaction (see Fig. 143.5).

The adrenal gland also produces C21 steroids (e.g., progesterone). The plasma production rate at 0.75 mg/day is low, producing a low plasma progesterone concentration of 30 ng/dL. Although progesterone is weakly androgenic, it does not exert a significant effect on the prostate at the low concentrations present in normal male plasma. **In summary, under normal conditions, the adrenals do not support significant growth of prostatic tissue.**

Estrogens in the Male

The estrogen receptors (ERs) are differentially expressed in the prostate. In the mouse, ER-α is expressed early (1 week) in the stroma of the ventral prostate but by 2 weeks is preferentially expressed in the epithelia, and ER-α is absent altogether in the ventral prostate by 4 weeks. In contrast, ER-β exists in the epithelial compartment as the dominant ER by the fourth week. However, knockout mice for ER (both isoforms) are able to form grossly normal prostates, although fertility may be limited in the ER-α group (Couse et al., 2001). Only small amounts of estrogen are produced directly by the testes. In the plasma of young healthy human males, 75% to 90% of the estrogens are derived from the peripheral conversion of androstenedione and testosterone to estrone and estradiol through the aromatase reaction (see Fig. 143.5) (Horton, 1976; MacDonald, 1976). The androgenic C19 steroids (testosterone and androstenedione) are converted to the estrogenic C18 steroids first by removal of the 19-methyl group and then by the formation of an aromatic or phenolic steroid A ring (aromatase reaction), present in estradiol and estrone. Estradiol is formed from testosterone and estrone from androstenedione; these two estrogens are interconvertible. **The daily production of estradiol in the human male is 40 to 50 µg, and only 5 to 10 µg (10% to 25%) can be accounted for by direct testicular secretion** (see Table 143.2).

Androgen-Binding Proteins in the Plasma

Less than 2% of the total testosterone in human plasma is free or unbound; the remaining 98% is bound to several different types of plasma proteins (see Fig. 143.4). The plasma proteins that bind steroids include human serum albumin, sex hormone–binding globulin (denoted SSBG or SHBG), corticosteroid-binding globulin (also named *transcortin*), progesterone-binding globulin, and, to a lesser extent, α_1-acid glycoprotein. Under normal conditions, the total amount of testosterone bound to progesterone-binding globulin and α_1-acid glycoprotein is nominal and is usually ignored. SHBG levels are suppressed by circulating androgens as well as anabolic steroids and may be decreased by diabetes and obesity.

The regulation of the amount of androgen that is free is an important physiologic variable and varies in different species. **The total amount of steroid bound depends on two factors: (1) the *affinity* of the steroid to bind to a specific protein and (2) the *capacity,* which is the maximal potential binding when all of a binding protein is saturated with bound steroid. The capacity is governed by the amount of binding protein in the plasma.** Serum albumin has a relatively low affinity for testosterone, but, given its abundance, it has a high capacity. In contrast, SHBG has a high affinity for binding steroids, but the protein is present in relatively low concentrations; however, the plasma molarity of each binding protein exceeds the plasma molarity for total testosterone concentration. The majority of testosterone bound to plasma protein is associated with SHBG. For example, Vermeulen (1973) has calculated that in the normal human male, 57% of testosterone in the plasma is bound to SHBG and 40% is bound to human serum albumin. Less than 1% is bound to corticosteroid-binding globulin, and only 2% of the total testosterone is free (see Fig. 143.4). The normal plasma free testosterone level is therefore 12.1 ± 3.7 ng/dL or 0.42 nM; this non–protein-bound “free testosterone” is bioavailable to diffuse into the sex accessory tissue and into liver cells for metabolism. In addition, a large percentage of the SHBG is saturated, whereas only a small fraction of the total capacity of corticosteroid-binding globulin and albumin is used under normal conditions. As testosterone levels increase in the plasma, the order of increasing saturation of the plasma proteins proceeds from SHBG to corticosteroid-binding globulin to albumin. Therefore the binding of androgen is a dynamic equilibrium between various serum proteins. Because less than 5% of total testosterone is present in the free form, separate measurement of bound and free testosterone is typically not recommended, and in general only total testosterone is measured.

The total plasma levels of SHBG can be altered by hormone therapy. **Administration of testosterone decreases SHBG levels in the plasma,**

whereas estrogen therapy stimulates SHBG levels (Burton and Westphal, 1972; Forest et al., 1968; Vermeulen et al., 1969). Estrogen also competes with testosterone for binding to SHBG, but estrogen has only one third the binding affinity of testosterone. **Therefore administration of small amounts of estrogen increases the total concentration of SHBG, and this effectively increases the binding of testosterone and thus lowers the free testosterone plasma concentration.**

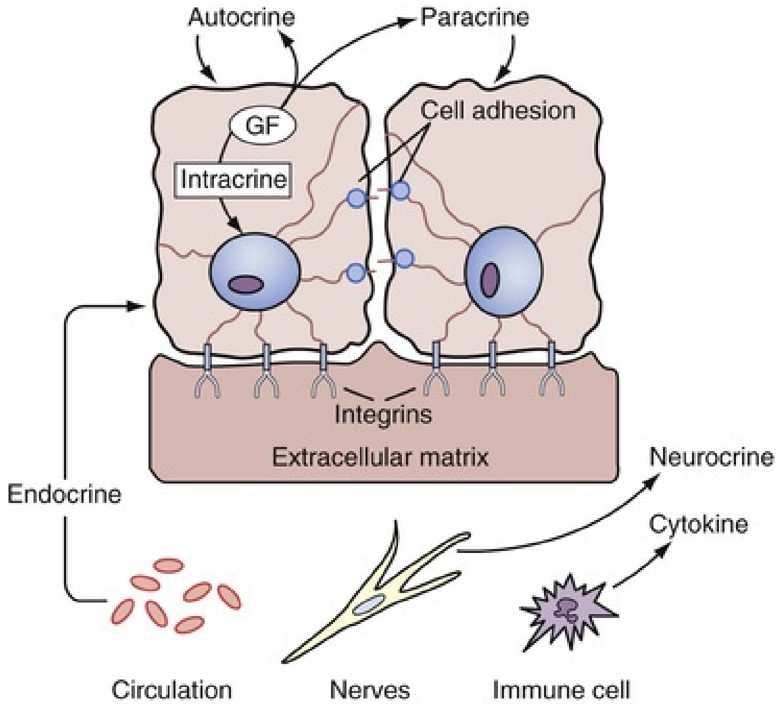
Because only free testosterone is bioavailable, the binding of testosterone to plasma proteins inhibits net testosterone uptake into the prostate (Lasnitzki and Franklin, 1972). It is apparent that androgenic activity is regulated in part by the extent of binding of an androgen to the steroid-binding proteins in the plasma.

Key Points: Endocrine Control of Prostate Growth

- Free testosterone in the plasma is converted in the prostate by 5α-reductase type 2 into DHT, which is 2 to 10 times more active than testosterone.
- DHT, testosterone, and estrogens are responsible for multiple metabolic actions in the prostate (growth, differentiation, and biologic functions). Free testosterone can be converted to estrogens, but estrogens cannot be converted to testosterone.

Regulation of Prostate Growth by Steroids and Protein Growth Factors

There are multiple levels of prostate growth regulation, which include steroid hormone action, growth factors, and direct cell-cell communication and interactions with the extracellular matrix. These interactive types of growth control are accomplished by several generalized systems, as depicted in the schematic in Fig. 143.6. They include the following:



Autocrine
Paracrine
GF
Intracrine
Cell adhesion
Integrins
Extracellular matrix
Endocrine
Neurocrine
Cytokine
Circulation
Nerves
Immune cell

FIG. 143.6 Types of growth control. Endocrine signals are carried through the circulation from distant organs. Paracrine signals are produced in proximity by neighboring cells. Autocrine signals feedback on the same cells from which they are produced. Intracrine signals are a special subset of autocrine signals that never leave the cell but rather act locally within that cell. Cytokines are paracrine-like factors (typically) that are made by immune cells. Neurocrine factors are released by nerves. Cell adhesion molecules directly link neighboring cells, often through association with cognate adhesion molecules. Cells are also bound to the extracellular matrix through interactions with other cell adhesion molecules (e.g., integrins). *GF*, Growth factor.

- *Endocrine factors* or long-range signals arriving at the prostate by serum transport of hormone originating from the secretions of distant organs; endocrine factors include serum steroid hormones such as testosterone and estrogens and serum peptide hormones such as prolactin and gonadotropins
- *Neuroendocrine signals* originating from neural stimulation, such as 5-hydroxytryptamine (serotonin), acetylcholine, and norepinephrine
- *Paracrine factors*, or soluble tissue growth factors that stimulate or inhibit growth, which are elaborated over short ranges between

neighboring cells within the prostatic tissue compartment (FGFs, epidermal growth factor)
- *Autocrine factors,* which are produced and released by a cell and then fed back on the same cell's external membrane receptors to regulate its own growth or function; for example, autocrine motility factor
- *Intracrine factors,* which function like autocrine factors but work inside the cell
- *Extracellular matrix factors,* which are insoluble tissue matrix systems and make direct and coupled contact by being attached through integrins and adhesion molecules of the basal membrane and couple cytoskeleton organization with the extracellular matrix components, which include the glycosaminoglycans, such as heparan sulfate (Getzenberg et al., 1990)
- *Cell-cell interactions* of the epithelial or stromal cells occurring through tight membrane junctions on intramembrane proteins such as the CAMs (e.g., E-cadherin) that couple neighboring cells

Of these seven growth control systems, the first extensively studied on the prostate was the endocrine effect of androgenic steroids, such as testosterone, in the regulation of prostate growth through changes in serum testosterone levels and conversion to DHT. However, androgens alone are not sufficient for full prostate growth. In the past two decades, extensive progress has been made in the understanding of the other systems, particularly the interactive role of growth factors and their receptors. At present, the roles of these receptors in cell signaling to the nucleus and of the structural elements in cellular control involving the tissue matrix are being developed. These mechanisms are reviewed next, starting with androgen action at the cell level beginning with the arrival of testosterone in the serum.

Androgen Action at the Cellular Level

Testosterone in the serum arrives at the prostate bound to albumin and to the steroid-binding globulins. By diffusion, free testosterone enters the prostate cell, where it is then subjected to a variety of steroid metabolic steps that appear to regulate the activity of the steroid hormone and its downstream effectors. A simplified schematic of the temporal sequence of intracellular events is depicted in Fig. 143.7 and includes the following:

Plasma

FIG. 143.7 Simplified schematic of the effects of testosterone in activating transcriptional targets in an epithelial cell. In the plasma, testosterone (T) is bound to serum-binding globulins (SBG), such as testosterone-binding globulin and albumin. Unbound testosterone is transported by passive diffusion into the prostate, where it is enzymatically converted to dihydrotestosterone (DHT) by 5α-reductase (type 2) and further metabolized to diols (3α or 3β) and irreversibly metabolized into the more water-soluble triols (6α or 7α). DHT binds to a cytoplasmic receptor (androgen receptor) that is activated and translocated to the nucleus. There the androgen receptor localizes in matrix acceptor sites and subsequently activates or represses certain target genes by regulating production of their mRNA. The RNA is then transported to the cytoplasm, where it is translated into a variety of proteins (e.g., secretory proteins such as prostate-specific antigen).

- Cellular uptake of testosterone
- Testosterone conversion to DHT by metabolism of 5α-reductase
- DHT or testosterone binding to specific ARs in the cytoplasm
- Dimerization and activation of the steroid receptor by a variety

of post-translational steps, including, for instance, phosphorylation

- Active nuclear transportation of the activated AR in an adenosine triphosphate (ATP)–dependent fashion
- Chromatin remodeling through interaction with coregulatory molecules
- Transactivation or transrepression, through interactions with other coactivators or corepressors, in a histone acetyltransferase–dependent process
- Binding of the activated receptor-coactivator complex to androgen response elements, which are short, specific sequences of DNA recognized specifically by AR dimers
- Gene regulation. The receptor acts as a transcription factor, and when it is bound to the DNA and matrix in proximity to androgen target genes, it increases the RNA polymerase II transcription of the DNA into mRNA. The transcribed message (mRNA) is large and contains introns, exons, and a poly-A tail. The intron portion is excised from the initial RNA species, so only the exon portion is retained in the final message. The trimming and processing of the mRNA are accomplished on the nuclear matrix as it is transported through the nucleus and out through the nuclear pore complex. The stabilized mRNA is transported into the cytoplasmic compartment to be translated at the ribosome into protein, which is then transported to specific cellular sites. Depending on the target gene, some proteins will undergo storage in secretory granules poised for secretion into the lumen on command during the physiologic process of ejaculation.

The epithelial cell is the primary unit in secretion, but specific genes are also activated in the stromal cells, and these events are also regulated by testosterone, estrogens, and growth factors in a similar chain of events. However, not all cells respond in the same manner to androgens or estrogens. For simplicity, these steps are discussed in relation to the epithelial cells. Androgens and estrogens, together and separately, can affect prostate cells through interaction with receptors, and it appears that estrogens may have their primary effect on the stromal cells.

5α-Reductase and Androgen Metabolism Within the Prostate

After the free testosterone in the plasma has entered the prostate cells through diffusion, it is rapidly metabolized to other steroids by a series of prostatic enzymes (Bruchovsky and Dunstan-Adams, 1985; Isaacs and Coffey, 1981; Isaacs et al., 1981, 1983). More than 90% of testosterone is *irreversibly* converted to the main prostatic androgen DHT (Fig. 143.8) through the action of the reduced form of nicotinamide-adenine dinucleotide phosphate (NADP) and the enzyme 5α-reductase located on the endoplasmic reticulum and on the nuclear membrane. The enzyme 5α-reductase reduces the unsaturated bond in testosterone between the 4 and 5 positions to form the 5α-reduced product DHT. The K_m for testosterone is 8.3 nM, and the serum level of testosterone is only in the range of 0.5 to 3.0 nM, indicating that the enzyme cannot be saturated because the testosterone substrate would be less than the K_m value. Bruchovsky and Dunstan-Adams (1985) reported a 10-fold increase in the maximal velocity in the stromal tissue compared with the epithelium. They observed 262 pmol of DHT formed in 30 minutes per milligram of protein from testosterone measured in the stroma and less than 10% of that amount with a maximal velocity of 19 for the epithelium. The stromal K_m was 76 nM, and the epithelial K_m was 13 nM. These differences between stromal and epithelial kinetics were used to deduce the existence of two different isoenzymes of 5α-reductase (Andersson et al., 1991).

FIG. 143.8 Metabolic pathways for testosterone within the prostate. Testosterone is irreversibly metabolized by 5α-reductase to dihydrotestosterone (DHT), which is then reversibly converted into 3α-diol and 3β-diol. The 3β-diol is irreversibly inactivated to the more soluble 6α-triol and 7β-triol. *3α-HSD,* 3α-hydroxysteroid dehydrogenase.

In the human, rat, and monkey there are two isozymes of 5α-reductase (Table 143.3). The human and rat 5α-reductase isozymes are composed of 254 to 260 amino acids with a molecular weight of 28 to 29 kD. These enzymes are *N*- and *O*-glycosylated and have a high percentage of hydrophobic amino acids that are distributed throughout the enzyme. The chromosomal localization of the human 5α-reductase isozyme genes has been reported; the type 1 enzyme is at the extreme tip of the short arm of chromosome 5, and the human type 2 gene is on the short arm of chromosome 2. There is a 49% homology between type 1 and 2 enzymes in the human. The properties of these enzymes have been reviewed in detail by Russell and Wilson (1994) and the effects on prostate growth by McConnell (1995). The effect of finasteride on 5α-reductase activity has been reviewed by Rittmaster (1994). The type 1 enzyme is in the skin and in the adult scalp and is believed to be involved in hair formation. It is present to lesser degrees in the prostate epithelium and stroma. This isoform is found in normal levels in men with congenital 5α-reductase deficiency. **The type 2 enzyme is mutated in 5α-reductase deficiency and is the dominant isoform present in the prostate gland.** The type 2 enzyme appears in the basal cells of the epithelium and in the stromal cells but is absent in the secretory epithelial cells. This has raised the possibility that DHT stimulation of epithelial cells is derived from DHT converted within the stromal or basal cells. Silver et al. (1994) have studied the cell type–specific expression of these reductases, as well as their regulation. It appears that the 5α-reductase type 2 in the prostate does not change dramatically in individuals undergoing short-term androgen ablation.

Berman et al. (1995) have studied the distribution of the two 5α-reductase isozymes in the urogenital tract of the fetal rat. At 17 to 21 days of development the expression of type 1 gene predominated in the epithelial cells; the type 2 gene was limited to the mesenchymal cells. This is true in the testosterone-dependent and DHT-dependent anlagen of the urogenital tract. These investigators observed that androgens could stimulate the expression of the type 2 gene in the urogenital tract but not of the type 1 gene. They suggested that the type 2 5α-reductase gene exhibits positive feedback control in that the product of the enzyme, DHT, can stimulate expression of the gene; however, no evidence for such regulation of either 5α-reductase gene was detected in the fetus.

In summary, 5α-reductase is of great importance because the product DHT is important in the differentiation of the prostate during fetal development and because mutations in 5α-reductase give rise to a rare form of pseudohermaphroditism. In prostate physiology, expression of the 5α-reductase gene is regulated by androgens in the prostate and liver. It is also believed that 5α-reductase is involved in male pattern baldness, acne, and hirsutism as well as in BPH. **The 5α-reductase inhibitors finasteride (type 2 inhibitor) and dutasteride (type 1 and 2 inhibitor) are clinically useful drugs in the treatment of BPH and male pattern baldness when they are given to appropriate patients.**

After DHT is formed from testosterone in the prostate, it is then subjected to a series of reversible metabolic reactions to form 3α-diol (5α-androstane-3α,17β-diol) and 3β-diol (5α-androstane-3β,17β-diol) (see Fig. 143.8). The enzymes that perform this transformation of DHT are 3α- or 3β-hydroxysteroid oxidoreductases. These enzymes use NADP as a cofactor, but in contrast to 5α-reductase they can also use nicotinamide-adenine dinucleotide (NAD). The equilibrium for the metabolism of DHT favors the formation of DHT, that is, the 3-hydroxy group of 3α-diol and 3β-diol is oxidized to the 3-ketone that is present in DHT. It is known that 3α-diol administered to animals is a strong androgen through its rapid conversion to the effective DHT. On the other hand, 3β-diol is not effective as an androgen because it is rapidly and irreversibly converted to the triol form by hydroxylation in the 6α or 7α position (see Fig. 143.8). The triols are dead-end products of testosterone metabolism but are water soluble and inactive as androgens because they cannot re-form DHT. Steroids also can form glucuronide or sulfate conjugates and be secreted in a more soluble form. **In summary, testosterone is irreversibly metabolized to DHT that is in equilibrium with other reduced steroids primarily through oxidation and reduction at the 3 position. The steroids are inactivated by being irreversibly hydroxylated to the inactive triols.**

Androgen Regulation of Stromal-Epithelial Interactions

It is now apparent that there is a dynamic and reciprocal interaction between the functions of epithelial cells and those of stromal cells (Cunha, 1994; Cunha et al., 2003, 2004; Sikes et al., 1995; Steiner, 1993). These crosstalk interactions are mediated through the spatial organization of extracellular matrix elements that form the basement membrane linkage. This linkage presents, filters, and organizes the two-way paracrine signals and the flow of information between those two cellular compartments. For example, fluids, gases, nutrients, hormones, and many growth factors arriving in the prostate through the circulation must first pass through the stromal ground substance, the extracellular matrix, and the basement membrane before reaching the base of the secretory epithelial cells. Early in development, the functions of the epithelial and mesenchymal (stromal) elements vary as to their cell types, compositions, properties, and interactions. It is the integrated system biology of these two tissue elements as well as their dynamics during aging that play a vital role in the prostate's functions as a unit and gland. Indeed, it is the breakdown of these tissue interactions that is one of the hallmarks of the abnormal growth of the prostate that starts very early in life and is initiated at some time just after maximum virilization, at approximately 25 years of age. The prostate is extremely susceptible to permanent early alterations in form and structure as a consequence of genetic, environmental, dietary, or metabolic factors with aging (Risbridger et al., 2005). In fact, it is essential to establish the link between hormonal (androgens and estrogens) changes that occur during the fetal or neonatal period that *imprint* and hence may result in onset of late-life disease. With aging, during a period of 50 to 60 years, this organ slowly progresses through the transition from normal zonal histologic anatomy and function to the early signs of BPH, to prostatic inflammatory atrophy, to prostatic interepithelial neoplasia, and finally to various types of prostatic adenocarcinoma. This concept has been thoroughly documented in several rodent models (Naslund and Coffey, 1986, 1987; Prins et al., 2001; Prins and Birch, 1995; Rajfer and Coffey, 1978, 1979; Risbridger et al., 2005; Singh et al., 1999).

Cell Adhesion Molecules

Cell-cell and extracellular matrix interactions are becoming major targets for understanding how the phenotype of a cell is regulated. Transmembrane receptors on the cell surface extend through the plasma membrane and form a bridge directly connecting the cytoskeleton with proteins and receptors located within the extracellular matrix or on neighboring cells. The CAMs are divided into four major types: (1) integrins, which link the cell to the basement membrane and extracellular matrix components through heterodimer interactions; (2) cadherins, which link the cell to neighboring cells through homotypic polymers; (3) selectins, which link the cell to carbohydrate moieties primarily on the vascular system; and (4) immunoglobulin (Ig) superfamily adhesion molecules. The most extensively studied of these CAMs in the prostate in order of interest have been E-cadherins, which bind PrECs to one another, and CD71, which binds to transferrin, as well as several of the integrin molecules. These bindings have been surveyed in prostate tumor cell lines in vitro (Rokhlin and Cohen, 1995), but more extensive work must be carried out in vivo in the normal developing prostate and in prostate cancer.

The integrins are made up of two covalently linked heterodimers termed *α* and *β subunits.* These integrins externally contact the extracellular matrix receptors of fibronectin, fibrinogens, collagen, and laminin as well as glycosaminoglycans in the proteoglycans of the extracellular matrix. The integrin receptor domains inside the cell compartment are focal points for determining the structure and organization of the cytoskeleton. Approximately eight subunits of α and β can interact in different heterodimers that are tissue specific and can be of several types even on one cell. Different combinations may have varying degrees of binding activity for extracellular matrix components. For example, $\alpha_3\beta_1$ binds to laminin, collagen, and fibronectin and does so by recognizing a triplet of amino acids in those proteins made up of arginine, glycine, and aspartic acid (RGD).

Other types of transmembrane receptors also extend out of the cell to make direct cell-cell contact with the neighboring cell by recognizing similar receptors and forming homodimer bonds. Certain homophilic dimers that require calcium for interactions to form cell-cell bonds with neighboring cells are termed *cadherins.* Four of the cadherin types have been cloned. They contain 723 to 748 amino acids that are composed of a single peptide, an extracellular region with three repeated domains, a hydrophobic transmembrane region, and a long cytoplasmic tail. There is approximately 50% homology across species and between integrins. The cadherins are classified into three subtypes: E-cadherins, found in adult epithelial cells (also earlier termed *uvomorulin*, cell CAM 120/80, ARC-1, or L-CAM); N-cadherins, found in neural tissues of muscle (also termed

A-CAM); and P-cadherins, found primarily in placenta and epithelium (Albelva, 1994). In the prostate cell, for example, E-cadherins extending out of the surface membrane make contact with the neighboring cell and form a homodimer, and the E-cadherin extending inside the cell by passing through the membrane would form as an organizing center that binds a complex of three cytoplasmic proteins termed *catenins* α, β, and γ. This complex is localized to the zonula adherens of the cell and participates in junction formation and stabilization of the cytoskeleton. These interlocking matrix systems interact to form a structural network extending externally from cell-cell contact and the extracellular matrix interactions and then internally to cytoskeleton organization and centrally, terminating by direct contact with the nuclear matrix that forms tissue-specific DNA organization.

The interactions of the nonhistone tissue matrix regulate many aspects of DNA functions involved in growth and differentiation (Boccardo et al., 2003; Getzenberg et al., 1990). The nonhistone proteins such as high-mobility group (HMG) proteins include HMGI/Y (HMGA), which participates in numerous cellular processes, such as regulation of inducible gene transcription, integration of retroviruses into chromosomes, and induction of malignant transformation (Reeves and Beckerbauer, 2003). Through protein-DNA and protein-protein interactions, the members of the HMGA family can influence growth, cell proliferation, differentiation, and cell death; they influence chromosome dynamics by acting as architectural transcription factors affecting several genes that have an impact on tissue structure and organization. This class of genes is often upregulated in cancer (Reeves and Beckerbauer, 2003). These types of tissue matrix interactions are essential to the understanding of stromal-epithelial interactions because they form direct structural linkages and communications between the stroma and the epithelial nuclear DNA. In summary, under the influence of hormones (estrogens and androgens) and diet, it is the regulation of chromatin structure and organization through the histone and nonhistone pathways that replaces and maintains the tissue organization as well as interactions in health and disease.

The discussion, to this point, has concerned primarily insoluble elements in inducing stromal-epithelial interactions, but soluble hormones such as steroids, vitamins, and growth factors are also important (Sikes et al., 1995). The prostate stromal cells contain steroid receptors and respond to androgens and estrogens (see earlier discussion). Androgens and estrogens can alter the formation of collagen (Coffey and Walsh, 1990) and other extracellular matrix components, such as glycosaminoglycans, in the prostate (DeKlerk et al., 1984; DeKlerk and Human, 1985; Horsfall et al., 1994; Kofoed et al., 1990).

In summary, different components of matrix interactions can have either an inhibitory role in negative regulation of normal prostate growth or a positive role in establishing tumor growth. There have been many hypotheses concerning the mechanism of these epithelial-stromal interactions, but they have yet to be fully resolved.

Key Points: Cell Adhesion Molecules

- Transmembrane receptors on the cell surface extend through the plasma membrane and form a bridge directly connecting the cytoskeleton with proteins and receptors located within the extracellular matrix or on neighboring cells.
- The CAMs are divided into four major types: *integrins,* which link the cell to the basement membrane and extracellular matrix components through heterodimer interactions; *cadherins,* which link the cell to neighboring cells through homotypic polymers; *selectins,* which link the cell to carbohydrate moieties primarily on the vascular system; and Ig superfamily adhesion molecules.

Regulation of Prostate Growth at the Molecular Level: Steroid Receptors

In almost all cells in the body, steroids can enter the nucleus, but only a few cells can retain this steroid within the nucleus for any length of time. The cells that retain the steroid have receptors that are steroid specific, which can regulate specific steroid-sensitive genes within the nucleus to alter the expression of certain proteins. The AR's affinity for the nuclear acceptor site to which it binds in the nucleus is probably a compilation of binding to specific sequences on DNA (androgen response elements) as well as tissue-specific binding to coregulatory factors. The uptake and binding of the AR in the nucleus are regulated by the presence of the androgen ligand bound to the receptor, resulting in receptor activation. When androgens are not present, the receptor decreases its affinity for nuclear binding and can easily be removed; indeed, under castrate conditions, receptors may leak back out into the cytoplasm (Husmann et al., 1990). Immunohistochemical techniques indicate that in the presence of androgen the AR localizes primarily to the nucleus.

The prostate and seminal vesicles contain steroid-specific and high-affinity (10^{-9} to 10^{-10} M K_d) saturable (100 to 1000 fmol of receptor per milligram of DNA equivalents of tissue) ARs that were first described by Liao and Fang in 1969. There are 5000 to 20,000 molecules of these receptors per cell, far more than can bind to the androgen response element sites, which are probably fewer than 400. Classic AR function has been characterized as a genomic process, wherein certain transgenes are regulated by the activated AR. More recently, however, attention has been focusing on the nongenomic mechanisms of androgen action (Benten et al., 1997; Jones et al., 2004). Nongenomic androgen action is characterized by extremely rapid changes in cellular physiology, typically measured in seconds or minutes, as opposed to the longer times required for target gene regulation to be translated into protein changes. Whether nongenomic androgen action occurs through the same ARs involved in genomic regulation still remains to be determined. The properties and hormonal regulation of ARs as well as their uses have been reviewed in detail (Black and Paschal, 2004; Gelmann, 2002; McEwan, 2004).

Androgen Receptor

The cloning of the human AR and its expression was a hallmark in the study of the mechanism of androgen action (Chang et al., 1988b; Lubahn et al., 1988). This led to the study of the sequence of the gene and its protein product—and how this is altered in inherited androgen insensitivity syndromes—as well as receptor function (Chang et al., 1995).

The *AR* gene is on the long arm of the X chromosome at position Xq11.2-q12. Because there is only one X chromosome in a male, it is a single-copy gene. The coding sequence on this gene is divided into eight exons that are transcribed and processed into mRNA and then subsequently translated into protein. The total genomic DNA spans a minimum of 80 kilobases (Marcelli et al., 1990) but forms a final message of only 10.6 kilobases, that is, only 17% of the total gene, with an open reading frame of 2757 base pairs. This is similar to the organization of many other steroid receptors that also contain information from eight exons, such as the progesterone and ERs. The AR is a member of the nuclear receptor superfamily, which is a group of ligand-inducible transcription factors. The nuclear receptor superfamily has more than 200 members at present (Escriva et al., 2004). All of these receptors share certain structural features that allow them to regulate gene expression, although the ligands for many of these receptors have yet to be identified (so-called orphan receptors). Such receptors include the glucocorticoid receptor, the retinoic acid receptors (RXR and RAR), the vitamin D receptor, the estrogen and progesterone receptors, the peroxisome proliferator-activated receptor (PPAR-γ), and many orphan receptors. Like other steroid receptors, the AR is divided into three distinct, modular domains: the amino-terminal domain, the DNA-binding domain, and the carboxyl-terminal ligand-binding domain. Despite the similarity in structural organization of all of the nuclear receptors, activation of different receptors results in markedly different cellular responses. Mutational analyses of the human AR have allowed a detailed mapping of a variety of different functions, which are diagrammed schematically in Fig. 143.9.

FIG. 143.9 Structure of the human androgen receptor protein. The androgen receptor is divided into several functional domains including the DNA-binding domain (consisting of two zinc fingers), a steroid-binding domain (consisting of a hydrophobic pocket), a nuclear localization motif, and several coactivator-corepressor binding sites. There are three polymorphic repeats of glycine, proline, and glutamine, with varying sizes among different populations. The relative positions of the functional elements are shown to scale.

Upstream (5′ direction) of the transcriptional initiation site is the regulatory element of the gene that controls its expression. It is unusual in that it contains the GC box rather than the classic TATA and CCAAT, which are commonly found in promoters of polymerase II–dependent genes. Closer to the initiation site located only 70 base pairs upstream is a 50–base pair purine-rich region that is a *cis*-acting element for AR transcription. There are other *cis*-acting elements, including an AP-1 (which is bound by a heterodimer of c-Fos and c-Jun) and a RARE (retinoic acid response element) as well as a cyclic adenosine monophosphate (cAMP) response element (AR/CRE1). This suggests that the regulation of expression of the *AR* gene may involve cAMP, activation of c-Fos/c-Jun, or retinoids (Faber et al., 1993; Kuiper et al., 1989; Mizokami et al., 1994; Young et al., 1994). Activation of the AR appears to be a function of multiple steps, including initial complex formation with certain chaperonins, binding of ligand, post-translational modifications, dimerization, nuclear localization, and binding of the receptor to certain transcriptional coactivator complexes that remodel chromatin, target the initiation site, and stabilize the RNA polymerase II machinery for repeated rounds of transcription. Each of these features is discussed in the context of known structural features of the receptor as diagrammed in Fig. 143.10.

FIG. 143.10 Mechanism of androgen receptor (AR) activation by ligand. Androgen enters the cell membrane by passive diffusion and binds the androgen receptor in the cytoplasm. The AR exists in equilibrium with the chaperonin complex, consisting of at least eight different components,

including Hsp90, Hsp70, Hip, p60, p23, FKBP51, FKBP52, and Cyp40. Once activated by binding ligand, post-translational modifications occur, such as phosphorylation. Contemporaneously, dimerization occurs, and the activated modified androgen receptor is translocated to the nucleus by active transport.

Chaperonin Binding.

Immediately after nascent production of the protein in the ribosome, the receptor forms complexes with several other proteins, referred to as *chaperonins*. These chaperonins form an aggregate complex, which is known as the *8S complex*, in reference to the size of the complex on sucrose gradient sedimentation analysis. This chaperonin complex includes at least eight known components (Hsp90, Hsp70, Hip, p60, p23, FKBP51, FKBP52, and Cyp40), which sequester the receptor into an inactive pool (see Fig. 143.10). By analogy to the progesterone receptor, which has had the most detailed scrutiny in regard to the molecular biology of the chaperonin complex (Nair et al., 1996; Pratt and Toft, 1997; Smith, 2000), the AR can dissociate into a monomeric form (4S on sucrose gradient centrifugation) that is in equilibrium with the 8S form, with the preponderant species existing in the chaperonin complex. This larger complex may be particularly favored by virtue of mass action alone, because the heat shock proteins tend to be among the most abundant proteins in the cell. Although the AR is uncomplexed, it is susceptible to various different post-translational processing steps, including phosphorylation or glycosylation. Such interactions may then inhibit reassociation with the chaperonins, leading to ligand-dependent activation, ligand-independent activation, or receptor inactivation with proteasome-mediated degradation. Evidence for such a mechanism includes a PEST sequence similar to one in the vitamin D receptor that is present in the hinge region of all known mammalian ARs, suggesting that it may function in proteasome-mediated AR turnover. Moreover, proteasome inhibition leads to a significant increase in AR isoforms (Sheflin et al., 2000).

DNA-Binding Domain.

Near the end of exon 1 and extending into exon 3 is the coding sequence for the DNA-binding domain. The DNA-binding domain of the AR consists of 72 amino acids rich in cysteine and encoding two zinc finger motifs, which allow specific recognition of certain DNA sequences referred to as *androgen response elements*. Such elements typically consist of a palindromic repeat separated by a three-nucleotide spacer—for example, GG(A/T)ACAnnnTGTTCT (Roche et al., 1992). X-ray crystallography of certain steroid receptors (glucocorticoid receptor and progesterone receptor) has shown that the first zinc finger directs sequence specificity of binding by directly contacting the DNA bases in the major groove; the second zinc finger functions to stabilize the protein-DNA complex by contacting the sugar-phosphate backbone. Although the protein-DNA interaction appears to be largely limited to the zinc finger motifs, sequences in the amino terminus appear to be important in stabilizing these structures because mutations in this region result in a mildly diminished DNA-binding affinity. This DNA-binding domain of the zinc fingers in the steroid receptor molecule is highly conserved. In this region of exon 2 to 3, there is a 79% homology with the progesterone receptor, a 76% homology with the glucocorticoid receptor, and a 56% homology with the ER (Chang et al., 1988a, 1988b). The closest homology of the AR is with the progesterone receptor (Lubahn et al., 1988; Marcelli et al., 1990). Mutations of amino acids in this area of the AR can make the receptor unable to activate androgen-sensitive genes (Govindan, 1990), which is the basis of one of the inherited androgen-insensitivity syndromes—testicular feminization.

The DNA-binding domain binds to its cognate DNA-regulatory site, referred to as a *hormone response element.* Hormone response elements can be divided into different groups on the basis of common structural features for which whole groups of receptors are capable of binding. Class I hormone response elements include the glucocorticoid receptor, the progesterone receptor, and the mineralocorticoid receptor and are characterized by a half-site consensus sequence of TGTTCT. Class II hormone response elements include the ER, whose prototype half-site sequence is TGACC. The hormone response elements to which ARs have been shown to bind belong to the class I subgroup (Tan et al., 1990). A consensus sequence for the androgen response element has been determined by an RNA-binding site selection assay with an AR fusion protein to be GG(A/T)ACAnnnTGTTCT (Roche et al., 1992). Such binding sites are characterized by an inverted palindromic repeat with a dyad axis of symmetry, indicating that the receptors are binding in a head-to-head fashion. However, the androgen response element of the rat probasin promoter has been found to be a direct repeat (Schoenmakers et al., 2000). Surprisingly, x-ray crystallography data reveal that AR dimers bind to direct repeat target sequences in a head-to-head fashion, maintaining the normal orientation of an inverted repeat target sequence (Shaffer et al., 2004). Only the AR has been found to bind to a direct repeat target sequence with an orientation normally expected for an inverted repeat. This difference may represent one way ARs maintain specificity of target gene regulation.

Ligand-Binding Domain.

Ligand-dependent activation is characterized by ligand-receptor dimerization, post-translational modifications (e.g., phosphorylation), nuclear translocation, and subsequent target gene activation (or repression). It is believed that binding of either DHT or testosterone to the ligand-binding domain can facilitate these processes, although the binding affinity for DHT is significantly higher than for testosterone. Binding of the androgen to the carboxyl-terminal ligand-binding domain is required for activation; however, deletion of the ligand-binding domain can lead to a constitutively active AR. In prostate cancer, various splice isoforms have been identified that lead to constitutively active function (Hu et al., 2011). Thus at least part of the interaction with the chaperonin complex involves the carboxyl portion of the receptor (Marcelli et al., 1990). However, small point mutations in the ligand-binding region can lead to significant changes in the characteristics of AR action. For instance, a single-point mutation in the ligand-binding domain of the AR (codon 877, Thr → Ala) identified in the LNCaP cell line of prostate cancer renders it weakly inducible by inappropriate steroids such as progesterone while it retains the ability to be stimulated by androgens. Marcelli et al. (1990) reported that mutations in the AR at amino acid 587 or 794 are inactive in the assay for androgen binding and for transcriptional activation. However, the removal of amino acids from 708 to the carboxyl end at 917 (i.e., the entire ligand-binding domain) leads to the synthesis of a receptor protein that does not bind androgens but is still constitutively active in activating transgenes. As new drugs have become available for prostate cancer androgen axis suppression, resistance to these new agents (e.g., abiraterone and enzalutamide) may involve some of the AR splice isoforms, or potentially even upregulation of other steroid receptors (Sharifi, 2014).

Dimerization.

The identification of the palindromic structure of certain hormone response elements for all steroid receptors led to the proposal that these transcription factors bind to the DNA as a dimer. Subsequent analysis of the receptor-DNA interactions has confirmed this hypothesis, and dimerization is now thought to represent an important step in the regulation of steroid receptor action. A hydrophobic heptad repeat within the ligand-binding domain at codons 859 to 880 is conserved among all steroid receptors and is thought to be necessary for high-affinity dimerization. Removal of these sequences leads to low-affinity dimerization, presumably through the action of the DNA-binding zinc fingers on the palindromic androgen response elements. Abolishment of the DNA-binding domain does not inhibit the strong affinity dimerization present in the ligand-binding domain. The strong dimerization signal appears to be related to a hydrophobic α-helix interface formed by the conserved heptad (Centenera et al., 2008).

Post-Translational Modifications.

Once the AR has been bound to steroid ligand and dissociated from the chaperonin complex, it is susceptible to a variety of post-translational modifications, any one of which may significantly affect the function and turnover of the receptor. For instance, the AR can be acetylated (Fu et al., 2004) or phosphorylated (Goueli et al., 1984). In the rat ventral prostate it has been reported that this occurs through a nuclear cAMP-dependent protein kinase (Kemppainen et al., 1992). Receptor phosphorylation may be an important mechanism in the nuclear translocation of steroid receptors as well as in DNA binding and transcriptional regulation. The stimulation for phosphorylation appears to be optimal with the binding of an androgen agonist, because antagonists such as flutamide appear to favor the dephosphorylated state, suggesting that the phosphorylation status may be associated with the ultimate activity of the receptor (Wang et al., 1999). Serine and tyrosine residues have been found to be phosphorylated in other steroid receptors (Landers and Spelsberg, 1992; Sadar et al., 1999). In addition to phosphorylation by protein kinase A, ARs also appear to stimulate mitogen-activated protein kinases, which may provide a different level of regulation of gene activity because such kinases often modulate other transcription factors, such as Elk-1 (Peterziel et al., 1999). The prostate is a rich source of acid phosphatases, and some have suggested that these enzymes may be active in regulating the phosphotyrosyl residues of the AR, thus playing a role in dephosphorylation and inactivation of ARs (Goldsteyn et al., 1989), although this relationship is certainly not causal.

Nuclear Localization.

After activation by the binding of steroid ligand the AR is transported to the nucleus across the nuclear pore complex by a process involving at least two nuclear localization signals, one for import and one for nuclear export. Evidence for nuclear localization signal-dependent nuclear translocation is well established and can be found in a variety of nuclear proteins, including the SV40 large T antigen. In most cases it consists of a stretch of basic amino acids. The prototype nuclear localization signal from the SV40 large T antigen is PKKKRKV, although various other basic sequences have also been implicated in nuclear localization signaling. The nuclear localization of the AR appears to involve multiple steps, including the binding of the basic amino acid nuclear localization signal to importins α and β, docking of an importin-cargo complex to the nuclear pore, translocation to the nucleus, and Ran-GTP–mediated release of the cargo (Rao et al., 2002).

Two regions of steroid receptors have gained most attention as regulators of receptor trafficking. The first region is the second DNA-binding zinc finger region, together with the flanking hinge region (NL1) consisting of a bipartite signal including flanking leucines and the core signal ^{628}RKLKKLGN (Kemppainen et al., 1992; Poukka et al., 2000; Ylikomi et al., 1992). However, this one putative nuclear signal peptide is not sufficient by itself for high-efficiency translocation, and by analogy to other steroid receptors, additional nuclear localization signals may exist in the steroid-binding domain (Kemppainen et al., 1992). NL1 acts constitutively and participates in rapid nuclear import that is facilitated by importin-α binding (Savory et al., 1999). A number of coregulators of steroid receptor–mediated transactivation interact with regions that encompass NL1 (Jackson et al., 1997; McKenna et al., 1999; Moilanen et al., 1998; Powers et al., 1998). Some of these proteins, such as SNURF and Ubc9, lose their ability to interact with AR when the region overlapping with the bipartite NL1 is destroyed (Moilanen et al., 1998; Poukka et al., 2000). A second signal, NES^{AR}, is located in the ligand-binding domain (Saporita et al., 2003) and is a nuclear export signal that facilitates export of AR when it is not complexed to ligand. Between the NL1 and NES^{AR}, the AR is actively shuttled between the cytoplasm and nucleus, presumably to tightly regulate its intrinsic ability to activate or repress gene expression.

Transcriptional Activation Domains.

Once the AR has achieved active localization into the nucleus, it must find and bind to its target sequences in the genomic DNA. The precise mechanism by which receptor localization occurs to target genes is still unknown; however, there is emerging evidence indicating it is a highly orchestrated process

(O'Malley, 2008). For instance, it is now known that so-called pioneer factors such as FOXA1 are targeted to specific chromosomal sites by epigenetic signaling, and then the ARs bind to these sites to subsequently regulate the target genes (Lupien et al., 2008). Once the AR has properly localized within the target chromatin sites, it must coordinate binding to a number of associated factors referred to as *coactivators* and *corepressors* that subsequently regulate gene expression (Fig. 143.11). A list of recently identified coactivators is provided in Box 143.1. Most of these factors interact promiscuously with many steroid receptors, although more AR-specific factors are routinely being discovered. Because the number of potential coregulators clearly exceeds the capacity for direct interaction by a single receptor, the most likely mechanism is that transcriptional activation by AR involves multiple factors that act in a sequential and a combinatorial manner to reorganize chromatin templates (Pollard and Peterson, 1998). The precise timing and sequence of binding of these factors remain to be elucidated; however, in general, one can break down the processes empirically into chromatin or nucleosomal remodeling (an energy-dependent process), histone acetyltransferase activity, and subsequent recruitment of TATA-binding protein (TBP)–associated factors, all of which promote an increased rate of gene transcription by RNA polymerase II. Under certain conditions, such as binding of an AR antagonist (e.g., flutamide), the histone acetyltransferase activity is actually inhibited and transrepression may occur. Such inhibition of gene expression appears to involve the nuclear corepressor proteins N-CoR and SMRT (Glass and Rosenfeld, 2000). Other proteins may play a similar role, such as the *HBO1* gene (Sharma et al., 2000). Amino-terminal deletions in region 46-408 result in dominant negative suppression of hormone-inducible transgene activation, indicating that the coactivator functions require an interaction within that site and that in the absence of this region the receptor forms dysfunctional complexes in the chromatin (Palvimo et al., 1993).

FIG. 143.11 Mechanism of action of the nuclear-activated androgen receptor (AR). Once the androgen receptor has been translocated to the nucleus, it undergoes several steps (many of which may occur contemporaneously): (1) chromatin remodeling in an adenosine triphosphate (ATP)–dependent fashion via the SWI-SNF complex and (2) agonist (i.e., dihydrotestosterone [DHT])-mediated histone acetylation in a process involving multiple transmission factors including p300, CBP, and SRC1. In the case of a certain antagonist, histone deacetylation may be favored, and the activated nuclear receptors complex with repressors of gene expression such as N-CoR and SMRT. (3) The activated androgen receptor complexes then associate with other γ-*trans*-acting factors via the TRAP/DRIP (thyroid receptor-associated protein/D receptor–interacting protein) complex at sites typically upstream of the target gene known as *androgen response elements.* This complex then leads to androgen-regulated activation of gene expression.

The transcription domain of the AR is coded in exon 1, which is the largest of the exons, containing 1607 base pairs. Analysis of this region reveals three homopolymeric repeated regions, including a repeat of approximately 20 glutamines, followed by a space containing 8 repetitive prolines and 23 repetitive glycine units (see Fig. 143.11). The glutamine repeats form a β sheet that helps form a polar zipper, which favors certain protein-protein interactions. Fusion of this type of polymeric glutamine repeat with the DNA-binding domain of GAL4 in yeast results in a GAL4-directed increase in transcriptional activity, demonstrating the importance of this region in promoting transgene activation (Gerber et al., 1994).

Studies demonstrate that these polyglutamine repeats appear to interact directly with the carboxyl terminus of the transcription factor p160 (Irvine et al., 2000). In the normal population this repeat varies over a length of 11 to 31 residues, resulting in a true allelic polymorphism. This means that different people have alleles of variant polyglutamine repeat units. This variation is racially defined, and it has been suggested that this may be related to the differences in the incidence rates of prostate cancer in different ethnic groups. The most common CAG repeat length in Caucasians is a modal value of 21; in African-Americans, it is shorter at 18; and in Asians, it is longer at a mean of 23. The longer the glutamine repeats, the lower the activity of the AR in activating target genes. Patients with X-linked spinal and bulbar muscular atrophy, termed *Kennedy disease,* possess a larger glutamine repeat in the range of 40 to 60. The ARs in Kennedy disease exhibit markedly less transactivation activity (Laspada et al., 1991). Moreover, men with male factor infertility are found to have longer than average polymorphisms of the AR than normal controls (Tut et al., 1997). Genetic studies of inherited diseases of androgen insensitivity and overvirilization as well as changes in the AR mutation associated with prostate cancer and its biologic properties will be of great help in unraveling the role of the human AR in relation to its structure.

Key Points: Androgen Receptor

- The AR, an intracellular steroid-binding protein, is activated by androgens, resulting in genomic and nongenomic actions, which in turn regulate cellular action.
- This regulation is central to prostate development, growth, and homeostasis and occurs in the stromal and epithelial compartments.

Androgen Receptor–Dependent Chromatin Remodeling

Part of the tissue and gene specificity in the recognition of receptors and DNA may depend on the organization of the DNA within the nucleus (Getzenberg et al., 1990). The steroid-receptor complex can interact only with genes that are in regions that are “open” or in the transcriptionally active form. Studies show that these open regions of chromatin (euchromatin) can extend up to 100,000 base pairs in length, or more than 10-fold the size of a typical gene, which usually ranges from 1000 to 10,000 base pairs. It is unknown how such a large range of

DNA is altered in conformation, but it may be through binding to structures such as the nuclear matrix, which can order large loop domains in the region of 60,000 to 120,000 base pairs. Nuclear receptors are thought to interact with chromatin remodeling complexes in an ATP-dependent fashion, in a process directed in part by “pioneer factors” including FOXA1 (Lupien et al., 2008), and this may be among the earliest steps in the ultimate regulation of certain target genes (Glass and Rosenfeld, 2000).

During cell division, chromosomal organization is spatially regulated at each of the critical phases of mitosis (Williams and Fisher, 2003). Epigenetic regulation of chromosome structure and function is highly ordered during cell division, differentiation, and development (Lam et al., 2005; Margueron et al., 2005). In fact, chromosomal proteins are required to maintain such ordered structure for euchromatin, heterochromatin, and centromeric chromatin to sustain normal cell and tissue functions. To achieve such coordinate regulation, the protective packaging of DNA is engineered through an elegant system of tightly wound DNA around an eight-component histone core called a *nucleosome*. This core consists of dimers of H2A, H2B, H3, and H4, whose ability to compact DNA is directly regulated by post-translational modifications. The selective regulation of such post-translational histone modification constitutes a major regulatory mechanism for gene expression and is referred to as the *histone code* (see Fig. 143.11). Histone modifications include acetylation, phosphorylation, ubiquitinylation, and methylation (Cosgrove et al., 2004; Cosgrove and Wolberger, 2005; Downs and Jackson, 2003; He et al., 2003; Lam et al., 2005).

ARs are known to interact with structural components of the chromatin organizing complexes. Such complexes include the multisubunit human SWI-SNF complex, which has been shown to remodel mononucleosome and polynucleosome templates in an ATP-dependent manner (Peterson and Tamkun, 1995). The isolated hSWI-SNF ATPase subunits BRG1 and hBRM also have these activities (Phelan et al., 2000).

The transcriptional activation of nuclear receptors (neuroendocrine cells) requires multiple factors, including SWI-SNF complex, CPB/p300, and steroid receptor coactivator (SRC) family members, which are large and contain numerous subunits, many of which make contact with a variety of nucleosome components and the nuclear matrix (Huang et al., 2003). Such components include BAF53a, BAF57, BAF60, BAF110, BAF155, BAF170, BAF250, BRG1, BRM, and SNF5. Because condensed chromatin renders genes inaccessible for transcription, the combination of a steroid receptor and SWI-SNF complex formation appears to be critical for appropriate nucleosomal remodeling to allow appropriate target genes to be accessible for gene regulation (Huang et al., 2003; Sudarsanam and Winston, 2000). Once the receptor SWI-SNF complex, CPB/p300, and other mediators have successfully “opened” the structure of the chromatin to allow transcriptional regulation, the AR must interact with a distinctly different set of cofactors.

Post-translational histone modification clearly appears to be requisite for chromosome remodeling and optimal gene expression (Ewen, 2000; He et al., 2003). In most models tested the rates of gene transcription actually correlate with the degree of modification of histones through acetylation, phosphorylation, ubiquitinylation, and methylation. In other words, hyperacetylated histone regions correspond to the highest gene-transcriptional regions, whereas the hypoacetylated histone regions correspond to the lowest gene-transcriptional regions (Pazin and Kadonaga, 1997). A number of histone acetyltransferase complexes have been found to be associated with nuclear receptors, including the AR. These complexes include p/CAF, a homolog to the yeast GCN5, which participates in the yeast SAGA complex. This complex includes factors that possess activity but also TBP and a number of TBP-associated factors. The p/CAF protein has been found to be associated with the retinoic acid receptor and may be involved with multiple nuclear receptors. It is also known to bind to other histone acetyltransferase (HAT) proteins, including CBP/p300, which is known to acetylate not only histones but other transcription factors as well. The CBP/p300 complex is an essential coactivator for many genes and may actually serve as a molecular scaffold in stimulating gene transcription (Huang et al., 2003; Marshall et al., 2003; McKenna et al., 1999). Such complexes include the SRC1 coactivator, among others. More recently, the modifiers of the histone code have expanded considerably to include sophisticated enzyme-mediated alterations in the histones H2A, H2B, H3, and H4 by phosphorylation, ubiquitinylation, and methylation, which open the chromatin, allowing the recruitment of important transcription factors that allow normal cell functions (Lam et al., 2005; Margueron et al., 2005).

The list of coactivators associated with nuclear receptors and the AR in particular is extensive and almost certainly incomplete. A short list of factors found to be associated with the receptor at this level of gene regulation is given in Box 143.1. Among the most important factors is SRC1, which has mild HAT activity and seems to be required for optimal stimulation of steroid-dependent transcription. Additional factors include steroid receptor RNA activator (SRA), a structural RNA necessary for the coactivator complex to function optimally (McKenna et al., 1999), and p160 coactivator, which appears to be required for hormone-dependent activation and to directly interact with the polyglutamine repeats found in the amino-terminal transactivation domain (Irvine et al., 2000).

Most genes have a regulatory region immediately upstream of the transcriptional start site. The regulatory region is divided into a core *promoter element* that is present in all genes as well as other upstream elements that serve to regulate the overall gene expression pattern. This promoter element specifies the site to which RNA polymerase II will attach to the DNA and will determine the actual point for the initiation of transcription. The RNA polymerase will copy or transcribe the DNA code into mRNA, a process termed *transcription.* This promoter area starts at −16 nucleotides to +32 upstream from the gene initiation site. This region of −32 to +16 was originally referred to as the *Goldberg-Hogness box* or *TATA box* and has a consensus sequence of TATAAAAG. The RNA polymerase II enzyme binds to this TATA box as one of the initial steps in transcription. Farther upstream from the TATA box is a second gene control element termed generically the *hormone response element*, which has been identified in many genes regulated by steroid hormones and is one of multiple sites where the receptor binds to the DNA. As stated earlier, in androgen-regulated genes, this area is termed the *androgen response element;* in estrogen, the *estrogen response element;* and in glucocorticoid, the *glucocorticoid response element.* This hormone response element area may contain several discrete sequences, but its overall role is to modulate the frequency of transcription initiation vis-à-vis interactions with transcriptional factors. In independent analysis, thyroid hormone receptors were found to be associated with affinity purified proteins, which were found to markedly enhance ligand-dependent cell-free transcription. This complex was referred to as *TRAP*, for thyroid receptor-associated proteins (Fondell et al., 1996). In a similar set of experiments, the same type of complex was isolated for the vitamin D receptor and was called DRIP for D receptor–interacting proteins (Rachez et al., 1998). Subsequent analysis revealed that they shared at least nine proteins, and this activator-recruited cofactor complex (TRAP/DRIP/ARC) is part of a large composite coactivator complex used by a variety of transcription factors for the regulation of certain target genes. Such transcription factors include sterol regulatory element-binding protein (SREBP), nuclear factor-κB (NF-κB), and VP16 (Gu et al., 1999; Ito et al., 1999; Naar et al., 1999; Ryu et al., 1999; Sun et

al., 1998).

In summary, the TATA box tells where RNA polymerase binds and where the initiation of transcription is to start and the hormone response element regulates how frequently it is to be transcribed when it is bound to a hormone receptor. This is accomplished by the presence of certain cofactors in the TRAP/DRIP complex. Because the hormone response element of DNA sequence has been shown to be independent of its position or its orientation, it resembles what has been called the *transcription enhancer element* that has been found in many other types of genes. The hormone response element section can vary in its location upstream from the initiation of the gene from −20 to −6000 for various different types of hormones. With the steroid hormones, it appears to reside about −140 nucleotides upstream from the initiation site. For example, in the glucocorticoid receptor recognition element, the site for glucocorticoid receptor recognition is approximately −140 and contains a sequence of nucleotides of AAAATGGAC. Deletion mapping experiments have indicated that the receptor-binding domain located in the hormone response element is indeed required for receptor binding and is necessary for steroid-mediated control of transcription.

Once the DNA is transcribed into mRNA, a series of adenine units are added to the end (called the *poly-A tail*) and then the mRNA is cut and spliced on small nuclear particles (called *spliceosomes*) located on the nuclear matrix, and this splicing removes the intron portion of the message. The final mRNA is shipped out of the nucleus, believed to occur on the structural components of the nuclear matrix, and passes through the pore complexes of the nucleus and out to the ribosomes where the mRNA is then translated into protein product, a step termed *translation.* The proteins have specific amino acid sequences that instruct the cell where to ship the protein in relation to secretory granules or to the membrane area. The protein can also be modified after translation by the subsequent addition of carbohydrates to become glycoproteins or to be phosphorylated by kinases. Under appropriate signals, such as neurologic control, secretory proteins can then be excreted into the lumen of the prostate. This is a process that occurs when secretory proteins of the prostate and seminal vesicles are formed into the ejaculate. A schematic example of this process is shown in Fig. 143.7, and such a system would include PSA and acid phosphatase as well as many other protein products that are regulated in their synthesis by androgens through receptor interactions.

During embryonic development, the AR appears first in the mesenchyme of the rat ventral prostate and seminal vesicles and a few days later in the epithelial cells, but it is unknown what regulates this timing. **In the development of the seminal vesicles and the wolffian duct, testosterone appears to be the primary androgen in glandular development, and in the ventral prostate that forms from the urogenital sinus the androgen is primarily DHT.** Testosterone and DHT can bind to the AR; however, on a molar basis, DHT is 3 to 10 times more potent. This decrease in potency of testosterone is believed to be caused by the rapid off rates of the testosterone once it is bound so that equilibrium results in less receptor occupancy compared with DHT at similar tissue levels. A report indicates that, in some cases, AR-mediated transcriptional regulation can occur even in the absence of direct interaction of the AR with the specific androgen response elements (Kallio et al., 1995). The report stated that the ARs are able to elicit transrepression and transactivation without interacting directly with the specific DNA elements. This may indicate that the AR can bind to regulatory units within the transcription factors and thus alter their properties even in the absence of direct DNA binding to an androgen response element.

The next part of this discussion is focused on the structure of the nucleus, where the genetic information of the genes, the AR interactions, and the mRNA processing occur and are integrated. This is within a highly ordered structure of the nucleus that is determined by a residual scaffolding framework, called the *nuclear matrix,* which provides three-dimensional organization to the nucleus and the DNA.

Role of the Nuclear Matrix in Androgen Action.

The DNA may be identical in every cell of different tissues in the body, but it appears to be organized in a different three-dimensional array in different cell types. This spatial organization of DNA appears to be determined in part by nuclear architecture and structure dictated by the scaffolding element termed the *nuclear matrix.* Therefore more may be required than just a steroid receptor and a DNA sequence with an androgen response element to determine the high tissue specificity of androgen hormone action. It may require regulation of DNA conformation and three-dimensional structure. There is strong evidence to support the belief that structural components of the nucleus may organize the DNA into different topologic constraints that permit specific steroid receptor interactions themselves. It is also believed that these structural modifications of DNA topology may be an integral part of differentiation. The nuclear matrix has been proposed to be an important structural element in this type of DNA organization (Boccardo et al., 2003; Getzenberg et al., 1990). The matrix facilitates the location of target genes and their conformation and facilitates their cointeraction with steroid receptors. Barrack and Coffey first showed that the nuclear matrix is a major target for androgen and ER binding (Barrack, 1987; Barrack and Coffey, 1980). Because the matrix has been implicated in many important nuclear events, it would provide an ideal target for androgen action. The nuclear matrix has been defined as the dynamic structural subcomponent of the nucleus that directs the functional organization of DNA into loop domains and provides sites for the specific control of nucleic acids (Getzenberg et al., 1990; Nelson et al., 1986). Conceptually, it can be viewed as the nuclear equivalent to the cytomatrix or cytoskeleton. The nuclear matrix contains residual nuclear elements, including the pore complex lamina, the residual nucleolus, and an internal ribonucleoprotein particle network attached to a dynamic fibrous protein mesh (Berezney and Coffey, 1977). The nuclear matrix may be isolated by sequential extractions using nonionic detergent, brief digestion with DNase I, and a hypertonic salt buffer wash. The residual nuclear matrix structures represent only 15% or less of the original total nuclear mass. More than 98% of the DNA, 70% of the RNA, and 90% of the nuclear proteins have been extracted, and the remaining structure is essentially devoid of histones and lipids.

The nuclear matrix has been implicated as an important structural component in a wide variety of biologic functions. There are approximately 50,000 DNA loop domains in a nucleus, each containing about 60 kilobase pairs of DNA, and these loops are attached at their bases to the nuclear matrix (Luke and Coffey, 1994; Pardoll et al., 1980; Vogelstein et al., 1980). This loop organization is maintained during interphase and throughout metaphase (Nelson et al., 1986). Topoisomerase II, an enzyme that modulates DNA twisting and topology, is associated with the nuclear matrix and the mitotic chromosome scaffold. Many studies with a wide variety of systems have demonstrated that active genes are associated with the nuclear matrix, whereas transcriptionally inactive genes are not close to the matrix. This location of active genes on the matrix provides evidence that the matrix plays an important organizing role in differentiation, placing genes in different configuration.

Androgens can activate DNA synthesis and cell replication in target tissues. The nuclear matrix also serves an important role in DNA replication. The matrix contains fixed sites for DNA synthesis (Pardoll et al., 1980) located at the base of the DNA loop. During DNA synthesis the DNA loop domains are reeled down through the attached replicating complex that is fixed on the matrix. Therefore the DNA replication fork, DNA polymerase, and newly replicated DNA have been shown to be associated with the nuclear matrix. It is easy to visualize how hormone action and alteration in the nuclear matrix structures could impinge on the androgen regulation of DNA synthesis and growth in a prostate cell.

The nuclear matrix is also associated with mRNA synthesis during transcription. Ciejek et al. (1982) observed that more than 95% of the unprocessed mRNA precursor for ovalbumin is associated with nuclear matrix of the chick oviduct. When the intron portions of the RNA were spliced out, the mature mRNA was released from the nuclear matrix. This led them to suggest that the nuclear matrix is involved in RNA processing. Marriman and van Venrooij (1985) reported that all RNA cleavage products and RNA processing intermediates are firmly bound to nuclear matrix. Once again, alterations in nuclear matrix structures with steroid receptor interactions could alter important steps in transcription and RNA processing. The nuclear matrix contains the attachment sites for the small nuclear ribonucleoprotein particles that are part of the nuclear spliceosome system central to the nuclear processing of RNA to the final mRNA, which is transported out to the cytoplasm to be translated.

Ahmed and colleagues have carried out an extensive series of studies of the phosphorylation of the nuclear matrix and related proteins in the ventral prostate of the rat after androgen stimulation and withdrawal (Ahmed and Goueli, 1987; Ahmed et al., 1993; Tawfic et al., 1993, 1994). They have shown that the nuclear matrix can be phosphorylated by casein kinase 2 (CK-2). One of the targets of this phosphorylation is nucleolin, which is an abundant nucleolar phosphoprotein involved in the synthesis of ribosomal DNA and exquisitely regulated by androgens (Tawfic et al., 1994). Another important protein in nucleolar function that is required for growth is B23, which is also regulated by CK-2 (Tawfic et al., 1993).

In summary, the nuclear matrix is an important structural modulator of nuclear regulation and is an ideal target for hormonal regulation. Indeed, the nuclear matrix is a major site of steroid hormone receptor binding (Alexander et al., 1987; Barrack, 1987; Barrack and Coffey, 1982; Donnelly et al., 1983; Metzger and Korach, 1990; Luke and Coffey, 1994; Wilson and Colvard, 1984). In the prostate, more than 60% of all nuclear ARs are associated with the nuclear matrix (Barrack and Coffey, 1982). The matrix is also a target for many other types of regulatory interactions, including the nuclear products of oncogenes and viral proteins that can also induce growth regulation similar to hormone-induced growth. For example, the nuclear matrix is reported to be a cellular target for the retrovirus Myc oncogene protein and the polyoma large T antigen. All of these transformation proteins that bind to the nucleus are believed to be early molecular events in carcinogenesis or transformation. Therefore the observation that ARs interact with the matrix has precedence with the matrix as a common target in factors that regulate cell structure and function.

Key Points: Androgen Receptor Structure and Function

- The AR is a ligand-activated transcriptional regulator that, on binding to androgen dissociates from chaperonins, is actively modified by a variety of methods to an active stage, is actively translocated to the nucleus, and associates first with pioneering factors that direct where in the chromatin the receptor will function and then associates with a large number of coactivators and repressors to regulate target gene expression.
- The transport of the AR is reciprocal: it is localized to the nucleus and actively transported out of the nucleus.
- The AR binds to DNA target sequences as a dimer, which can be direct or inverted repeats; however, the receptor always binds with the same orientation.
- The regulation of the AR appears to be one of the most important “gatekeepers” of prostate development and physiology.

Prostatic Secretions and Proteins

Prominent, Nonpeptide Components of Prostatic Secretions

The seminal plasma is formed primarily from the secretions of the sex accessory tissues, which provide a suitable environment for survival and function of spermatozoa. The sex accessory tissues include the epididymis, ampullae, seminal vesicles, prostate, Cowper (bulbourethral) gland, and glands of Littre. **The average volume of the normal human ejaculate is approximately 3 mL, ranging from 2 to 6 mL, and it has two components: spermatozoa and seminal plasma. Spermatozoa, which represent less than 1% of the total ejaculate, are present in the range of 100 million/mL. The major contribution to the volume of seminal plasma (average 3 mL) comes from the seminal vesicles (1.5 to 2 mL), from the prostate (0.5 mL), and from the Cowper gland and glands of Littre (0.1 to 0.2 mL).** During ejaculation the secretions of these glands are released in a sequential manner (Amelar, 1962; Amelar and Hotchkiss, 1965; Tauber and Zaneveld, 1976; Zaneveld and Tauber, 1981). The first fraction of the human ejaculate is rich in sperm and prostatic secretions, such as citric acid. The level of fructose, which represents a major secretory product of the seminal vesicles, is elevated in the later fraction of ejaculate. More recently, seminal albumin was measured in seminal plasma, and the authors demonstrated an association with sperm morphology but not several other semen parameters (Elzanaty et al., 2007). The overall chemical composition of normal human and rodent prostatic secretions and seminal plasma has been widely studied, and the results have been summarized in excellent reviews (Aumuller and Seitz, 1990; Chow et al., 1993; Daniels and Grayhack, 1990; Elzanaty et al., 2007; Gonzalez et al., 1993; Mann and Mann, 1981; Zaneveld and Tauber, 1981). An analysis of expressed prostatic secretions in a small cohort of men revealed that citrate, myo-inositol, and spermine metabolite measurements could potentially differentiate controls from men with prostate cancer (Serkova et al., 2008), with tissue analysis also suggesting that spermine and citrate can distinguish benign from cancerous prostate (Giskeødegård et al., 2013).

In relation to other body fluids the seminal plasma is unusual because of its high concentrations of potassium, zinc, citric acid, fructose, phosphorylcholine, spermine, free amino acids, prostaglandins, and enzymes (most notably acid phosphatase, diamine oxidase, β-glucuronidase, lactate dehydrogenase [LDH], α-amylase, PSA, and seminal proteinase).

Citric Acid

One of the major anions in human seminal plasma is citrate (mean, 376 mg/dL), which is present in the range of 20 mM or 60 mEq/L. This is compared with the chloride ion (155 mg/dL) at 40 mM. Citrate is a potent binder of metal ions, and the seminal plasma concentration of citrate, 20 mM, is comparable with that of the total divalent metals at 13.6 mM (calcium, 7 mM; magnesium, 4.5 mM; zinc, 2.1 mM). Prostatic citrate levels approximate 15.8 mg/mL (Zaneveld and Tauber, 1981), and the values for seminal vesicle citric acid secretions are almost 100-fold less, being only 0.2 mg/mL. Citric acid is formed in the prostate at 100 times higher concentration than is seen in other soft tissues (e.g., prostatic tissue, 30,000 nmol/g; other tissues, range of 150 to 450 nmol/g). **The concentration of citrate in the ejaculate is 500 to 1000 times higher than that in the plasma. Prostatic secretory epithelial cells form citrate from aspartic acid and glucose. The high concentrations within the prostate result partly from the inability of the prostate cell mitochondria to oxidize citrate readily once it is formed; therefore the rate of citrate synthesis far exceeds the rate of citrate oxidation** (Costello and Franklin, 1989, 1994; Kavanagh, 1994).

Fructose

The source of fructose in human seminal plasma is the seminal vesicles (Mann and Mann, 1981). Patients with congenital absence of the seminal vesicles also have an associated absence of fructose in their ejaculates (Phadke et al., 1973). The seminal vesicle secretion contains smaller amounts of other free sugars such as glucose, sorbitol, ribose, and fructose, and these sugars usually amount to less than 10 mg/dL. In comparison, the concentration of the reducing sugar fructose is approximately 300 mg/dL in human seminal secretion, and it has a level of 200 mg/dL in seminal plasma. The fructose of the seminal plasma appears to provide an anaerobic and an aerobic source of energy for the spermatozoa (Mann and Mann, 1981) and has been indirectly linked to forward sperm motility and seminal viscosity (Gonzalez et al., 1993; Fabiani et al., 1995).

Fructose levels are under androgenic regulation, but many factors, such as storage, frequency of ejaculation, blood glucose levels, and nutritional status, can also affect seminal plasma concentration (Mann and Mann, 1981); these considerations may account for the wide variations encountered in different semen samples from the same patient. Furthermore, plasma levels of androgens do not always correlate with seminal plasma fructose levels; therefore these levels are not a reliable index of the androgenic state of the subject. Seminal fructose levels have also been proposed to be under sympathetic control (Kempinas et al., 1995; Lamano-Carvalho et al., 1993).

Polyamines

Polyamines are the most basic (positively charged) small organic molecules in nature. They occur ubiquitously in tissues at high concentrations and are believed to be involved in diverse physiologic processes that share a relationship to cell proliferation and growth. Indeed, polyamines can serve as growth factors for cultured mammalian cells and bacteria and as inhibitors of enzymes, including protein kinases.

The exact role of polyamines at the molecular level still eludes science, but they represent important biologic compounds and are found at high levels in the ejaculate. Polyamines may affect the gating and transport of substances through membrane channels. From a clinical perspective, polyamines (spermidine and spermine) have been investigated as markers of androgen deprivation therapy among men with advanced-stage prostate cancer (Cipolla et al., 1994). Other researchers (Heston, 1991; Kadmon, 1992; Love et al., 1993; Madhubala and Pegg, 1992) have investigated the role of polyamines in the pathophysiology of prostate cancer. The first and rate-limiting step in polyamine synthesis within the prostate is controlled by the enzyme ornithine decarboxylase (ODC). ODC gene expression has been demonstrated to be increased in BPH tissue (Liu et al., 2002). ODC can be inhibited by difluoromethylornithine (DMFO), which in turn inhibits polyamine synthesis. DMFO has been proposed as an agent for chemoprevention of prostate cancer (Kadmon, 1992).

Spermine levels in normal human seminal plasma range from 50 to 350 mg/dL and originate primarily from the prostate gland, which is the richest source of spermine in the body. Spermine $[NH_2–(CH_2)_3–NH–(CH_2)_4–(CH_2)_4–NH–(CH_2)_3–NH_2]$ is a basic aliphatic polyamine and, because of its four positive charges, binds strongly to acidic or negatively charged molecules such as phosphate ions, nucleic acid, and phospholipids. When semen is allowed to stand at room temperature, acid phosphatase enzymatically hydrolyzes seminal phosphorylcholine to form free inorganic phosphate ions, which then interact with the positively charged spermine and precipitate as large, translucent salt crystals of spermine phosphate. Polyamines can also form amide bonds and make their covalent addition to protein carboxylic groups (Williams-Ashman et al., 1975), and this modification may be involved in regulatory function.

There has been much interest in spermine and other related polyamines, such as spermidine and putrescine, because of the rapid and dramatic changes in levels and ratios associated with many types of cells that have been induced into growth. Williams-Ashman et al. (1969, 1972, 1975) have investigated in detail the biosynthesis and regulation of polyamines in the male reproductive tract and have characterized the enzymatic reactions that progress from ornithine to putrescine to spermidine to spermine. Polyamines are oxidized enzymatically by diamine oxidase (present in the seminal plasma) to form highly reactive aldehyde compounds that can be toxic to sperm and bacteria (Le Calvé et al., 1995). The formation of these aldehyde products produces the characteristic odor of semen. It is also possible that these aldehydes or polyamines may, themselves, protect the genitourinary tract from infective agents. Relationships between spermine levels in seminal plasma and sperm count and motility have also been suggested (Fair and Parrish, 1981; Fair et al., 1993; Le Calvé et al., 1995; Stamey et al., 1968). Like citrate, spermine can also be quantified within prostatic tissue by magnetic resonance spectroscopy (van der Graaf et al., 2000).

Phosphorylcholine

Other positively charged amines are at high concentrations in the ejaculate, including choline and phosphorylcholine, which are usually found as components of lipid or as lipotropic factors. The semen of mammals is rich in choline $[(CH_3)_3–N^+–(CH_2)_2–OH]$. In humans, phosphorylcholine predominates, whereas in most other species much higher levels of α-glycerylphosphorylcholine are present, often exceeding 1 g/dL of seminal plasma. Seligman et al. (1975) have demonstrated that phosphorylcholine is a highly specific substrate for PAP, which is also active in seminal plasma. The result of this enzymatic activity is the rapid formation of free choline in the first ejaculate. In contrast, α-glycerylphosphorylcholine is secreted primarily in the epididymis and is not readily hydrolyzed by acid phosphatase. For these reasons, Mann and Mann (1981) have suggested that the level of α-glycerylphosphorylcholine can be used as an index for assessing the contribution of the epididymal secretion to the ejaculate. The secretion from the epididymis is also under androgenic control. The function of these choline compounds is unknown; it appears that they are not metabolized by spermatozoa, nor do they affect the respiration of the sperm (Dawson et al., 1957).

Prostaglandins

The richest sources of prostaglandins in the human are the seminal vesicles (Pourian et al., 1995). Prostaglandins are present in seminal plasma at a total concentration of 100 to 300 µg/mL. Von Euler (1934) proposed the name *prostaglandins* for the active components in seminal plasma in the belief that they originated from the prostate gland, but Eliasson (1959) established that the primary source of prostaglandin is the seminal vesicles, not the prostate; however, the original name has survived. Prostaglandins have a wide distribution in mammalian tissues but at much lower concentrations than in the seminal vesicles (Vane and Botting, 1995).

There are more than 90 different prostaglandins present in the human, with 15 prostaglandins present in human semen, and they are all 20-carbon hydroxy fatty acids with a cyclopentane ring having two side chains; as such, they are derivatives of prostanoic acid. The 15 types of prostaglandins within the prostate are divided into four major groups, designated A, B, E, and F according to the structure of the five-membered cyclopentane ring. Each of these groups is further subdivided according to the position and number of double bonds in the side chain (therefore PGE_3 indicates prostaglandins of E type with three double bonds in the side chain). The E group of prostaglandins is the major component in the male reproductive tract, whereas the F group predominates in the female system. Fuchs and Chantharaski (1976) have summarized the reported levels of human seminal plasma prostaglandins and report the following mean values (µg/mL): PGE_1, 20; PGE_2, 15; $(PGE_1 + PGE_2) - 19\text{-OH}$, 100; $PGA_1 + PGA_2$, 9; $(PGA_1 + PGA_2) - 19\text{-OH}1$, 31; $PGB_1 + PGB_2$, 18; $(PGB_1 + PGB_2) - 19\text{-OH}$, 13; $PGF_{1\alpha}$, 3; and $PGF_{2\alpha}$, 4.

These compounds are potent pharmacologic agents that have been implicated in a variety of biologic events in the male, including erection, ejaculation, and sperm motility and transport, as well as in testicular and penile contractions. In addition, prostaglandins from seminal fluid deposited in the vagina have been reported to affect cervical mucus, vaginal secretion, and sperm transport in the female genital tract. Prostaglandin E has been related to the immunosuppressive effects of seminal plasma mediated through the extracellular organelles, or “prostasomes” (Kelly et al., 1991).

Zinc

The high level of zinc in human seminal plasma (140 µg/mL) appears to originate primarily from secretions of the prostate gland (488 ± 18 µg/mL) (Bedwal and Bahuguna, 1994). The prostate has the highest concentration of zinc (50 mg/100 g dry weight) of any organ. Byar (1974) has reviewed many of the early experiments and concepts related to zinc in the reproductive tract. Zinc levels are elevated or stable in BPH, whereas there is a marked decrease in zinc content associated with prostatic adenocarcinoma. The localization of zinc-65 in the human prostate by radioautography appears to be within the epithelial cells; however, in the lateral prostate of the rat, large quantities of zinc were also associated with the stroma and particularly with the basal membrane and the elastin protein component (Chandler et al., 1977). Oral intake of zinc does not alter zinc levels in prostatic fluid.

Many physiologic roles have been postulated for zinc since the classic studies of Gunn et al. (1956, 1965), who correlated endocrine effects on zinc uptake and concentration in the prostate of the rodent. There are many important zinc-containing metalloenzymes, but the concentration of zinc in the prostate probably exceeds that present in zinc-associated enzymes. Zinc is known to bind many proteins (Sansone et al., 1991). Johnson et al. (1969) characterized zinc-binding proteins in the prostatic secretion of the dog, on hydrolysis, as containing only eight types of amino acids. Heathcote and Washington (1973) described a zinc-binding protein in human BPH that was rich in histidine and alanine. Jonsson et al. (2005) suggested that one possible role of zinc in semen may be to regulate the activity of PSA by binding to semenogelins I and II and fragments thereof. There have been other studies on zinc-binding proteins from the prostate (Fair et al., 1976; Reed and Stitch, 1973), and additional information on these interesting proteins is needed.

An important role for zinc in prostatic secretion has been postulated in the studies of Fair et al. (1976), which suggest the direct role of zinc as a prostatic antibacterial factor. In the study of 36 healthy men free from bacterial prostatic infections, the mean value of zinc in the prostatic secretion was approximately 350 µg/mL, with a wide range of 150 to 1000 µg/mL. In comparison, the prostatic fluid obtained from 61 specimens collected from 15 patients with documented chronic bacterial prostatitis had a reduction of more than 80% and averaged only 50 µg/mL, with a range of 0 to 139 µg/mL. The authors proposed a lower limit of normal at 150 µg/mL. In addition, in vitro studies of free zinc ions at concentrations normally found in prostatic fluid have confirmed the bactericidal activity of zinc against a variety of gram-positive and gram-negative bacteria. However, a considerable portion of the zinc in the prostate appears to be bound to unique proteins, such as metallothionein, and it is not certain how this may alter the biologic properties of zinc (Suzuki et al., 1994, 1995). Yan et al. (2008) reported that assessment of decreased zinc in a normal human PrEC in vitro resulted in increased single-strand DNA breaks (Comet assay) and differential expression of several genes (Affymetrix HG-U133A gene chips) involved in cell cycle progression, apoptosis, transcription, and DNA damage response and repair. Therefore a zinc deficiency may compromise DNA integrity in the prostate. In prostate cancer the ability of prostate cells to accumulate zinc is lost during disease progression and may be in part caused by the genetic and epigenetic alterations produced by zinc depletion.

Prostatic Secretory Proteins

The predominant secretory proteins of the sex accessory tissues have been reviewed (Aumuller and Seitz, 1990; Aumuller et al., 1990; Diamandis and Yousef, 2002; Lilja, 1993a, 1993b; Rittenhouse et al., 1998; Saedi et al., 2001; Yousef and Diamandis, 2002). High-resolution, two-dimensional electrophoresis profiles of the major secretory protein markers from human ejaculate, seminal plasma, and prostatic secretions have been reported (Aumuller and Seitz, 1990; Carter and Resnick, 1982; Dube et al., 1987; Edwards et al., 1981; Rui et al., 1984; Tsai et al., 1984).

With regard to the prostate, several secretory proteins are found in abundance and have clinical significance. These include primarily PSA (human kallikrein 3 [hK3, protein; or *KLK3*, gene]) and human kallikrein 2 (hK2 or *KLK2*), but also prostase/*KLK-L1* (Clements, 2008; Lwaleed et al., 2004; Yousef et al., 1999), PAP, and prostate-specific protein (PSP-94), also called β-microseminoprotein (β-MSP). Table 143.4 lists some characteristics of the major secretory proteins in the sex accessory tissues.

TABLE 143.4

Major Proteins Secreted by the Sex Accessory Tissue

PROTEIN OR GENE IDENTIFICATION	**MOLECULAR WEIGHT (kD)**	**SEMINAL PLASMA (mg/nL)**	**ACTIVITY**
Prostate-specific antigen (PSA) (hK3 [protein] or *KLK3* [gene])	33–36	0.70	Serine protease; arginine esterase
Human kallikrein 2 (hK2 or *KLK2*)	28.4	0.012	In vivo activation of proPSA, arginine esterase
Human kallikrein L1 *(KLK-L1)*	Unknown	Unknown	Serine protease, also in testes, breast, adrenal, uterus, thyroid, and salivary glands
Human kallikrein 11	Approximately 40	0.002–0.037	Serine protease, also in breast, ovary, and prostate
Prostatic acid phosphatase (PAP)	102–106	0.3–1.0	Phosphotyrosyl protein phosphatase
Prostate-specific transglutaminase	17	Unknown	Involved in the formation of stable, functional peptide-bound glutamine and primary amine groups
Semenogelins I and II	50, 63	2 mM[a]	Have chymotrypsin-like activity; inhibit PSA activity in the semen
Prostate-specific membrane antigen (PMSA)	Approximately 120	Unknown	Has a structure identical to glutamate carboxypeptidase II and folate hydrolase I; found in kidney, testis, ovary, brain, salivary gland, small intestine, colon, liver, spleen, breast, and skeletal muscle
Prostate stem cell antigen (PSCA)	Approximately 24	Unknown	A prostate cancer–associated tumor antigen
			Northern blot and in situ data show that PSCA is predominantly prostate specific in normal tissues and is overexpressed in greater than 80% of prostate cancers
Prostate-specific protein (PSP-94), β-microseminoprotein (β-MSP)	10.7–16	0.6–0.9	Also found in epithelial cells of antrum of stomach
Immunoglobulins	160	0.007–0.022	Human IgG

C3 complement	Approximately 178	0.018	An integral part of the complement cascade (C3 activates alternate pathway)
Transferrin	77	0.18	A plasma protein that transports iron through the blood to the liver, spleen, and bone marrow

[a] Only given in mM concentrations.

Table 143.5 illustrates the number of sample, median, and ranges of components of prostatic secretions among normal male reproductive parameters.

TABLE 143.5

Components of Prostatic Secretions

VARIABLES	N	MEDIAN	RANGE
Age (yr)	916	34	20–64
Time of sexual abstinence (days)	916	4.0	1.0–60
Semen volume (mL)	916	4.0	1.0–15
Sperm concentration (×106 mL^{-1})	916	44	0.1–568
Total sperm count (×10^{6} mL^{-1})	916	167	0.4–2400
a (%)	916	14	0–80
b (%)	916	28	0–80
a + *b* (%)	916	50	0–90
c (%)	916	16	0–50
d (%)	916	33	0–100
Total *a* + *b* (×10^{6} per ejaculate)	916	83	0–1200
Normal forms (%)	916	5.0	0–20
Tail defects (%)	916	11	1.0–85
DFI (%)	267	15	3.0–90
HDS (%)	267	7.0	1.0–40
NAG (mU/mL^{-1})	506	6.0	1.0–15
PSA (mg/L^{-1})	900	890	66–3400 or higher
Zinc (mmol/L^{-1})	900	2.0	0–7.0
Fructose (mmol/L^{-1})	900	14	0–39
FSH (IU/L^{-1})	351	5.0	1.0–45
LH (IU/L^{-1})	351	3.0	1.0–13
Testosterone (nmol/L^{-1})	351	13	3.0–31
Inhibin B (ng/L^{-1})	351	150	14–450
SHBG (nmol/L^{-1})	351	26	2.0–88

DFI, DNA fragmentation index; *FSH,* follicle-stimulating hormone; *HDS,* high DNA stainability; *LH,* luteinizing hormone; *NAG, N*-acetylglucosamine; *PSA,* prostate-specific antigen; *SHBG,* sex hormone binding globulin.

Prostate-Specific Antigen

PSA is a secreted serine protease, first demonstrated in human prostatic tissue in 1970 (Ablin and Soanes, 1970), found in seminal plasma in 1971 (Hara et al., 1971), purified from prostatic tissue in 1979 (Wang et al., 1979), measured in the serum of men in 1980 (Kuriyama et al., 1980), cloned at the gene level in 1987 (Lundwall and Lilja, 1987), and widely used as a clinical marker of prostate cancer by 1988 (Chan et al., 1987; Oesterling et al., 1988; Seamonds et al., 1986; Stamey et al., 1987).

The discovery of PSA resulted from a search of the ejaculate and prostatic fluid by immunoprecipitation to find specific proteins for forensic use. In 1971 Japanese workers isolated, from the seminal plasma, a protein that was proved to be antigenically specific for semen; they reported its chemical and physical characteristics and termed it γ-*seminoprotein* (Hara et al., 1971). Several years later, in an attempt to develop this protein further as a forensic marker for semen identification, γ-seminoprotein was purified from human seminal plasma. These seminal proteins, initially called γ-seminoproteins, have now been shown by sequence to be the same as PSA.

PSA is a glycoprotein acting as a serine protease of molecular weight 33 kD that contains 7% carbohydrate (Watt et al., 1986) and is found almost exclusively in the epithelial cells of the prostate (Armbruster, 1993; Rittenhouse et al., 1998). It consists of a single polypeptide chain and contains 240 amino acids and an *O*-linked carbohydrate side chain attached to a serine residue (Watt et al., 1986). PSA acts physiologically like a serine protease and an arginine esterase with chymotrypsin-like and trypsin-like activity. The sequence of the protein is similar to that of other kallikreins (Rittenhouse et al., 1998) involved in prostatic cell regulatory mechanisms. Lilja (1985) and Watt et al. (1986) reported that one of the structural proteins of the seminal fluid, semenogelin, causes the ejaculate to clot. Semenogelin is the predominant seminal vesicle–secreted protein and one of the physiologic substrates for PSA. **One possible biologic role of PSA is to lyse the clot in the ejaculate, but it is at present unknown why this clotting and lysing mechanism is important to reproductive physiology.**

The PSA gene *(hKLK3)* is a member of a human tissue kallikrein gene family that includes *hKLK1*, *hKLK2*, *hKLK3*, and *KLK-L1* (Berg et al., 1992; Carbini et al., 1993; Clements, 1994; Lundwall, 1989; McCormack et al., 1995; McMullen et al., 1991; Nelson et al., 1999; Rittenhouse et al., 1998; Yousef and Diamandis, 2003). There are more than 15 different human kallikreins, with expression noted in prostate, breast, ovarian, and testicular cancers (Obiezu and Diamandis, 2005). These genes are located on chromosome 19 (Reigman et al., 1992; Yousef and Diamandis, 2003; Yousef et al., 1999). The ectopic expression of PSA has been reported in smaller concentrations in the tissue of malignant breast tumors (Yu et al., 1994a, 1994b, 1994c), normal breast tissue, breast milk, female serum, and adrenal and renal carcinomas; however, for practical and clinical purposes, PSA is an androgen-dependent and prostate organ-specific (but not a cancer-specific) marker. A limitation of PSA as a tumor marker is demonstrated in the substantial overlap in values between benign and malignant prostate disease (Oesterling et al., 1988; Partin et al., 1990).

Most work regarding the molecular biology and biochemistry of PSA is based on extensive study of purified protein from seminal fluid in which the concentration of PSA is nearly a million-fold higher than that found routinely in serum (McCormack et al., 1995). The concentrations found in seminal plasma range from 0.5 to 5.0 mg/mL, whereas normal serum concentrations in men aged 50 to 80 years without prostatic disease range from 1.0 to 4.0 ng/mL (Catalona et al., 1991).

Prostate-Specific Antigen Derivatives

PreproPSA (261 amino acids) is processed in the endoplasmic reticulum of prostatic epithelial cells, where a 17-peptide leader sequence is cleaved to form proPSA. Seven more peptides are then cleaved from the propeptide to form the active PSA peptide (Rittenhouse et al., 1998). The cleavage of the proPSA inactive (zymogen) precursor of PSA is performed primarily in vivo by hK2 (Lilja, 1985; Rittenhouse et al., 1998; Villoutreix et al., 1994). In addition to its cleavage at the −7 residue, proPSA can also be cleaved at the −2 or −5 residue to produce catalytically inactive PSAs termed *[−2]proPSA* and *[−5]proPSA*. Finally, additional forms of inactive PSA can be formed by internal cleavages at various regions within PSA (presumably occurring in the seminal fluid after PSA is secreted). These cleaved isoforms comprise BPSA.

A small proportion of active PSA diffuses into the circulation, where it is rapidly bound or complexed by covalent attachment to protease inhibitors (most commonly, α_1-antichymotrypsin) (Christensson et al., 1993; Lilja, 1993a; Lilja et al., 1991; McCormack et al., 1995; Partin and Carter, 1996; Polascik et al., 1999; Stenman et al., 1991). Inactive PSA can also enter the bloodstream, where it circulates in an unbound state as free PSA (fPSA).

Depending on the monoclonal antibodies used to measure serum PSA, the amounts of free and complexed PSA, as well as proPSA isoforms, can be detected. This has high clinical usefulness because the various PSA derivatives have associations with benign and cancerous prostatic tissue. In prostate cancer, the loss of gland architecture and basal cells results in a decrease in the luminal processing of proPSA to active PSA (and thus an increase in proPSA) and in addition a decrease in the processing of active PSA to BPSA (thus decreasing the amount of fPSA). Thus increased levels of BPSA in the serum are found in benign disease, whereas proPSA (and particularly [−2]proPSA) and bound PSA are associated with prostate cancer (Balk et al., 2003 and Tosoian and Loeb, 2010).

Human Kallikrein 2

Human kallikrein 2 (hK2 [protein] or *KLK2* [gene]) is a prostate-specific serine protease closely related to PSA (Rittenhouse et al., 1998). hK2 was first demonstrated from a low-stringency hybridization screen of a human liver genomic library in 1992, and the amino acid sequence is predicted to have 80% homology with PSA (hK3, *KLK3*) (Young et al., 1992). The striking homology between these two “prostate-specific” proteins suggested a close physiologic relationship. More recently, recombinant hK2 has been expressed and purified (Kumar et al., 1996; Mikolajczyk et al., 1998). Unlike PSA, hK2 is shown to be trypsin-like with selective cleavage at arginine residues and has a more potent (20,000-fold greater than PSA) protease activity (Mikolajczyk et al., 1998). Monoclonal antibodies to hK2 have been developed and have a low incidence of cross-reacting with PSA (Finlay et al., 1998). As mentioned earlier, physiologically, hK2 cleaves proPSA to generate the enzymatically active form of PSA in the prostate (Kumar et al., 1996). Immunohistochemical studies have shown hK2 to be increased in expression from normal to metastatic, poorly differentiated prostatic epithelium (Darson et al., 1997), and studies of hK2 in the serum of men with prostate cancer have suggested clinical usefulness for early detection of prostate cancer (Partin et al., 1999; Vickers et al., 2010).

Human Kallikrein L1

Attempts to find other novel human kallikrein-like genes on chromosome 19 have identified yet another member of the human kallikrein gene family, *KLK-L1* (Nelson et al., 1999; Yousef et al., 1999). Nelson et al. (1999) constructed a cDNA library enriched through subtraction with the cDNAs from four other normal tissues to yield an expressed sequence tag identifying a gene that they have called *prostase*. The sequence of prostase exhibits features similar to the other members of the kallikrein family. Yousef et al. (1999) also found *KLK-L1* in breast tissue and demonstrated that it is hormonally regulated. Although the clinical usefulness of the members of the kallikrein gene family has not yet been determined, it is under investigation.

Human Kallikrein 11

Human kallikrein 11 (hK11) is a serine protease that shares similarities to human kallikrein 3 (hK3) or PSA with significant homologies at the levels of nucleotide and protein structure (Diamandis and Yousef, 2002). Localization of hK11 in epithelial cells of various organs has been demonstrated immunohistochemically, and hK11 has been further detected in amniotic fluid, milk of lactating women, cerebrospinal fluid, follicular fluid, and breast cancer cytosols. The highest levels of hK11 were observed in prostatic tissue extracts and seminal plasma, in which it was present at 300-fold lower levels than PSA. Elevated serum levels of hK11 were found in 60% of men with prostate cancer; the ratio of hK11 to total PSA was able to reduce the number of biopsies required, and the data were similar to those gleaned from fPSA assays (Diamandis and Yousef, 2002; Nakamura et al., 2003).

Human Kallikrein 14

Human kallikrein 14, a trypsin-like human kallikrein–related peptidase (KLK), has been shown to exert a significant and dose-dependent effect on semen liquefaction (Emami and Diamandis, 2008; Emami et al., 2008). Liquefaction of human semen involves proteolytic degradation of the seminal coagulum and release of motile spermatozoa. Several members of human kallikrein–related peptidases are implicated in semen liquefaction, functioning through highly regulated proteolytic cascades. Among these, *KLK3* (also known as *prostate-specific antigen*) is the main enzyme responsible for processing of the primary components of semen coagulum. *KLK14* recently has been identified as a potential activator of *KLK3* and other KLKs (Emami and Diamandis, 2008; Emami et al., 2008). Borgono et al. (2003) measured seminal plasma levels of *KLK14* by an enzyme-linked immunosorbent immunoassay (ELISA) in 36 human semen samples and found *KLK14* to be 0.6 to 23.6 µg/L (mean 10.8; median 10.7 µg/L). Semenogelin I and semenogelin II are degraded by PSA to form various biologically active peptides involved in semen liquefaction and release of motile spermatozoa. Semenogelins I and II, through chelation with the excess of free zinc, are also directly cleaved by *KLK14*, in the same manner as PSA. In addition, *KLK14* has also been demonstrated to be a potential biomarker for ovarian and breast cancer (Borgono et al., 2003).

Key Points: Secretory Proteins—Kallikreins

- Secreted prostate proteases exert a significant and dose-dependent effect on semen liquefaction.
- Among the most well-studied secreted prostate proteins are hKLK3 (PSA) and a homologous protease, hK2, which functions to cleave PSA.
- PSA and its processed derivative (i.e., BPSA, fPSA, [−2]pro-PSA), as well as hK2, have various associations with benign prostatic tissue and prostate cancer and are currently being used to aid in prostate cancer screening.

Prostate-Specific Transglutaminases

Human prostate-specific transglutaminase 4 belongs to a family of enzymes that irreversibly cross-link peptide-bound glutamine residues through reactions with either lysines or primary amines such as polyamines (Dubbink et al., 1998). Transglutaminases are located throughout the body, but they are highly tissue specific. Dubbink et al. (1998) described a new prostate-specific transglutaminase with 35-kilobase genomic DNA and consisting of 13 exons and 12 introns. The main transcription initiation site is located 52 base pairs upstream of the translational start code. At least one splice variant has been described, and a transglutaminase 4 gene *(TGM4)* promoter was analyzed by sequencing and transfection experiments and found at −1276 to −563. Subsequently, an Sp1 binding site (promoter) required for basal activity of *TGM4* was identified (Dubbink et al., 1999). The *TGM4* promoter was characterized by deletion mapping and mutational analysis. These researchers determined that positions between −113 and −87 were essential for core activity of the promoter. The sequences identified are binding sites for the Sp1 and Sp3 transcription factors; however, their precise role in *TGM4* regulation was not deduced from experiments described (Dubbink et al., 1999). Of importance is the fact that the major gel-forming proteins in semen, semenogelins I and II, are substrates for transglutaminase 4 (Peter et al., 1998). Esposito and Caputo (2005) reviewed the range of substrates for transglutaminases in detail and characterized the molecular basis of transglutaminase-catalyzed reactions and assessed possible physiologic function and pathophysiologic processes resulting from such interactions. The transglutaminase for the prostate is transglutaminase 4; it weighs 77 kD, is androgen regulated, and is found extracellularly. Transglutaminases catalyze the post-translational modification of proteins by formation of polymerized cross-linkages between the γ-carboxamide group of protein-bound glutamine residues and the ε-amino group of protein-bound lysine residues, which results in a stabilized molecular complex. There is evidence to suggest that the biochemical affinity of transglutaminase 4 for acyl-type substrates such as kinesin proteins in protein secretions of the semen may be important for correct extrusion of transglutaminase 4 from the coagulating gland (Esposito and Caputo, 2005).

An et al. (1999) also described cloning of *TGM4* (human prostate-specific transglutaminase) and its promoter in the elements of −1 to −500 and also at −520 to −1400. In addition, this group applied Northern blot hybridization and reverse transcription polymerase chain reaction (RT-PCR) analysis to confirm prostatic specificity and Gleason grade-specific expression by RT-PCR and noted significant downregulation in high Gleason grade as well as in metastatic tissue extracts. From a protein perspective, Birckbichler et al. (2000) revealed by quantitative immunofluorescence that prostate cancer was significantly decreased compared with normal prostate and prostatitis patients, but this is in contrast to what was observed with RT-PCR results (An et al., 1999), in which the higher Gleason grade tumors tended to be significantly decreased. This discrepancy of results must be rectified in larger experiments comparing RT-PCR with protein expression to determine whether this is a technical problem or rather one of translation of transglutaminase 4 mRNA versus protein in the malignant disease process.

Semenogelins I and II.

Semenogelin I and semenogelin II are dominant proteins in human semen coagulum that are degraded by PSA to form various biologically active peptides, which in combination with fibronectin give rise to the gel-like coagulum of newly ejaculated semen (de Lamirande et al., 1997; Lilja, 1985; Malm et al., 1996). The genes encoding semenogelins I and II are located in separate regions 11.5 kilobase pairs apart on chromosome 20. The major biologic function of semenogelin involves **capacitation,** which is defined as a series of changes in cell membranes, enzyme activities, and ion fluxes that sperm undergo as they traverse the female urogenital tract to reach the zona pellucida and fertilize the egg (de Lamirande et al., 1997). It has been demonstrated that biologically active peptides from semenogelin I and semenogelin II proteolysis scavenge superoxide anion and may affect sperm oxidase to serve as natural regulators of sperm capacitation (de Lamirande, 2007; de Lamirande et al., 2001). Semenogelins from the seminal vesicles and zinc ions from the prostate play a significant role in semen aggregation at the time of sperm ejaculation and also in sperm motility by binding to the sperm and then interacting with zinc (de Lamirande, 2007; Yoshida et al., 2008). It is of physiologic and possibly pathophysiologic importance that these major gel-forming proteins in semen, semenogelins I and II, are substrates for transglutaminase 4 (Peter et al., 1998). Both of these proteins originate from the glandular epithelium of the seminal vesicles and are produced in high concentrations; however, in the epididymis, only semenogelin I is expressed. There is evidence by immunohistochemistry that other cell types, including the vas deferens, prostate, and trachea, demonstrate strong signals for semenogelins I and II, and weaker but positive signals were seen in skeletal muscle cells and in the central nervous system (Lundwall et al., 2002).

Prostate-Specific Membrane Antigen.

Reviews of the biochemistry and biology of the prostate-specific membrane antigen (PSMA) in human tissues and prostate cancer surveys describe the differential regulation of the molecule, its enzymatic functions, and its potential as a biomarker for in vivo imaging, targeted therapy, and immunotherapy (Elgamal et al., 2000; Ghosh and Heston, 2004).

The gene encoding PSMA is located on chromosome 11p11-12 and codes for a type II membrane glycoprotein (molecular weight approximately 100,000 Da) with intracellular (1 to 18 amino acids), transmembrane (19 to 43 amino acids), and large extracellular (44 to 750 amino acids) domains (Davis et al., 2005; Ghosh and Heston, 2004; Israeli et al., 1994). The cDNA (2.65 kb GenBank accession number M99487) encoding PSMA was first reported by Israeli and colleagues in 1994 and its deduced amino acid sequence determined (Israeli et al., 1994). It encodes a 750–amino acid protein with a predicted molecular mass of 84 kD (excluding carbohydrates). The hydrophobic amino acids found on amino acid residues 20 to 43 suggested that this protein is a type II integral membrane protein with a small intracellular domain and a large extracellular domain (Fair et al., 1997). The promoter for PSMA has been cloned (Good et al., 1999), and PSMA has been expressed and purified from a baculovirus expression system (Lodge et al., 1999). A portion of the transmembrane domain of this protein (amino acid residues 1250 to 1700) shares 57% homology with the human transferrin receptor mRNA (Mahadevan and Saldanha, 1999). Alternative splicing variants of PSMA (PSM′-PSA′ extracellular domain protein) are under investigation to better understand the clinical significance of this important membrane protein found within the prostate (Ghosh and Heston, 2004; Grauer et al., 1998; Liu et al., 1997; Murphy et al., 1998; Rajasekaran et al., 2005). PSMA has been crystallized and its structure deduced at 3.5-Å resolution. These analyses reveal a homodimer with structural similarity to the transferrin receptor, a receptor for iron-loaded transferrin that lacks protease activity (Davis et al., 2005). However, unlike the transferrin receptor, the protease domain of PSMA (glutamate carboxypeptidase II) contains a binuclear zinc site, catalytic residues, and a proposed substrate-binding arginine patch.

PSMA is strongly expressed in the prostate and is upregulated in prostate cancer and in the neovasculature of other tumors (Chang et al., 1999b, 2001; Silver et al., 1997). In the prostate there are three alternatively spliced variants of PSMA. However, only one of these isoforms (PSM′ located at the 5′ end of PSMA cDNA) is known to be differentially expressed in normal tissue, BPH, and prostate cancer (Elgamal et al., 2000; Rajasekaran et al., 2005). PSMA mRNA expression within prostate cancers is also in the hormone-deprived state, contrary to PSA mRNA, which often demonstrates lower, even absent, expression in the hormone-deprived state (Henttu et al., 1992; Israeli et al., 1994; Rajasekaran et al., 2005; Wright et al., 1995). The association of PSMA with prostate cancer makes it a favorable target for the development of imaging molecules and therapeutics (Chandran et al., 2008; Davis et al., 2005; Lupold and Rodriguez, 2004).

Despite its name, PSMA is also expressed in many nonprostatic tissues, including the kidney, salivary gland, small intestine, and nervous system. PSMA in the central nervous system metabolizes the brain neurotransmitter *N*-acetylaspartyl-glutamate or NAAG (named NAALADase). In the intestine, PSMA is found in the proximal small intestine, where it removes γ-linked glutamates from poly-γ-glutamated folate (folate hydrolase 1), or as a carboxypeptidase, glutamate carboxypeptidase II.

Prostate Stem Cell Antigen.

Reiter et al. (1998) identified prostate stem cell antigen (PSCA), a cell surface antigen that is expressed in the prostate (among other tissues including bladder). The *PSCA* gene encodes a 123–amino acid glycoprotein, with 30% homology to stem cell antigen 2 (Sca-2). Like Sca-2, PSCA is a member of the Thy-1/Ly-6 family and is anchored by a glycosylphosphatidylinositol linkage. **By use of mRNA in situ hybridization, PSCA expression was localized in normal prostate to the basal cell epithelium, the putative stem cell compartment of prostatic epithelium; hence PSCA may be a marker of prostate stem or progenitor cells.** Hara et al. (2002) performed an analysis of PSA, PSMA, and PSCA mRNA level on peripheral blood by RT-PCR in 58 patients with prostate cancer and 71 patients with nonmalignant disorders. The results were 7 of 58 (12.1%) for PSA, 12 of 58 (20.7%) for PSMA, and 8 of 58 (13.8%) for PSCA; zero samples were positive for nonmalignant diseases. A hierarchical summary of prognostic value for the three biomarkers was as follows: PSCA was higher than PSA, which was higher than PSMA for RT-PCR of the 58 patients with prostate cancer. Note that in this group of patients, when the RT-PCR result was positive for PSCA, the patients had a lower disease progression–free survival than with the other two biomarkers. The PSCA expression increased with higher Gleason score and cancer stage as well as with progression to metastasis and may be a useful biomarker for staging of prostate cancer (Hara et al., 2002). Han et al. (2004) performed immunohistochemistry analysis of PSCA by a 246-patient tissue microarray; the results revealed that a PSCA staining intensity of 3.0 correlated with adverse prognostic features including Gleason score of 7.0 ($P = .001$), seminal vesicle invasion ($P = .005$), and capsular involvement ($P = .033$). However, after multivariate analysis, PSCA did not hold up as an independent predictor of PSA recurrence. Zhigang and Wenlv (2004) studied BPH, low-grade prostatic interepithelial neoplasia (LGPIN), high-grade prostatic interepithelial neoplasia (HGPIN), and prostate cancer at the tissue level by immunohistochemistry and at the mRNA level by in situ hybridization. In BPH and LGPIN the staining of PSCA protein and mRNA was weak or negative and less intense and uniform than in HGPIN and prostate cancer. There was moderate to strong PSCA protein as well as mRNA expression in 8 of 11 (72.7%) HGPIN and in 40 of 48 (83.4%) prostate cancer specimens that were examined by immunohistochemistry and in situ hybridization analyses. When the prostate cancer specimens examined by immunohistochemistry and in situ hybridization analyses were compared with BPH (20%) and LGPIN (22.2%) samples, the results were statistically significant ($P < .05$, respectively). The expression level of PSCA increased with high Gleason grade, advanced stage, and progression to androgen independence ($P < .05$, respectively). In addition, in this study, protein immunostaining and in situ hybridization mRNA stain showed a high degree of correlation between PSCA protein and mRNA overexpression in prostate cancer, supporting the potential of PSCA as a prognostic biomarker. Clearly, the value of this protein to the biology of prostate epithelial tissue morphogenesis and also as a new biomarker for diagnosis and treatment of prostate cancer is yet to be realized.

The potential use of PSCA, a membrane surface antigen that is highly expressed in the prostate, as a novel prostate targeting medical device for diagnostics (blood immunoassays or medical imaging) and therapy (vaccines or immunotherapy) is currently being actively studied (Olafsen et al., 2007; Raff et al., 2009). Here is another unique opportunity to use prostate developmental knowledge as a possible tool to manage prostate cancer because of its amplification during carcinogenesis.

Prostatic Acid Phosphatase.

Acid phosphatase activity is more than 200 times more abundant in prostatic tissue than in any other tissue and is the source of the high levels of acid phosphatase in ejaculate. Phosphatase enzymes hydrolyze many types of organic monophosphate esters to yield inorganic phosphate and alcohol. Many phosphatase enzymes exhibit optimal activity in vitro in the acid (pH 4 to 6) or alkaline (pH 8 to 11) ranges and are thus classified broadly as either acid or alkaline phosphatase.

Acid phosphatase activity may be further defined by factors that inhibit its enzymatic activity. For example, erythrocyte acid phosphatase is particularly sensitive to inhibition by 0.5% formaldehyde or copper ions (0.2 mM), whereas PAP activity is far more sensitive to inhibition by fluoride ions (1 mM) or L-tartrate (1 mM).

Osteoclasts are also a rich source of tartrate-insensitive acid phosphatase. Minor elevations in serum acid phosphatase levels can accompany Paget

disease, osteoporosis, nonprostatic bone metastasis, and other conditions of increased bone resorption as well as metastatic prostate cancer. All acid phosphatases hydrolyze a wide range of natural and synthetic phosphomonoesters, and this has provided a wide variety of assay systems and the expression of different units of activity, depending on the assay. These synthetic substrates include, in part, phenylphosphate (Gutman and Gutman, 1938); phenolphthalein phosphate; paranitrophenyl phosphate, also called *Sigma 104;* and thymolphthalein phosphate (Roy et al., 1971). The specificity of these substrates varies with the type and source of acid phosphatase; it appears that thymolphthalein phosphate may be the most specific substrate for assaying serum levels of prostate-specific acid phosphatase, but specific antibodies are now available for immunoassays. Interest in acid phosphatase assays in serum as a measure of prostate cancer metastasis before definitive therapy has decreased with the availability of the more sensitive and specific PSA assay (Burnett et al., 1962).

The natural substrate for PAP may be phosphorylcholine phosphate, which is rapidly hydrolyzed in the semen (Seligman et al., 1951). The biologic functions of this enzyme and its reactions are not known, but it is of interest that PAP can hydrolyze protein tyrosine phosphate esters, natural products of many oncogene protein tyrosine kinases (Li et al., 1984; Lin and Clinton, 1986). By magnetic resonance spectroscopic techniques, it has been shown that the ratio of intracellular choline to citrate levels within the prostate can help differentiate normal from cancerous prostatic tissue (Scheidler et al., 1999). Further clinical testing is required before this finding will influence clinical practice. It is unknown whether acid phosphatase is a regulatory factor in the tyrosyl protein kinase systems that are so essential as signaling mechanisms in growth factor function.

Human PAP is a glycoprotein dimer of molecular weight 102,000 and contains about 7% carbohydrate by weight, composed of 15 residues per mole of neutral sugars (fructose, galactose, and mannose), 6 residues per mole of sialic acid, and 13 residues of *N*-acetylglucosamine (Chu et al., 1977). The protein can be dissociated into two subunits of 50 kD. The activity of the purified human enzyme is 723 U/mg with α-naphthyl phosphate, and the seminal plasma contains 0.3 to 1 g/L or 177 to 760 U/mL. The high enzymatic activity of PAP is not characteristic of accessory tissues in many other species; the level is 1000 times higher per gram of tissue in the human prostate than in the rat prostate. The clinical aspects of PAP were reviewed by Romas and Kwan (Lowe and Trauzzi, 1993; Romas and Kwan, 1993).

Prostate-Specific Protein 94 (β-Microseminoprotein and β-Inhibin).

A major, cysteine-rich, nonglycosylated 16-kD protein that contains 94 amino acids has been found in prostatic secretions and named *prostate-specific protein 94* (PSP-94); it is one of the three predominant proteins secreted in the prostate glands and found in seminal fluids along with PSA and PAP. This protein had previously been designated β-inhibin and also β-MSP (Dube et al., 1987; Ulvsback et al., 1989). Transcripts of mRNA for this protein have also been identified in nongenital tissues (Ulvsback et al., 1989). The human gene for PSP-94 has been mapped to chromosome 10 (q11.2), and there are three glucocorticoid response elements and one estrogen response element in the promoter region of the first intron. Based on these observations the gene is likely regulated by hormones in humans (Nolet et al., 1991; Ochiai et al., 1995) because this also was reported in studies of the rat lateral prostate (Kwong et al., 2000). Also, Valtonen-Andre et al. (2008) demonstrated that in young, healthy males the PSP-94 levels in the serum correlate well with those in the seminal plasma ($r = 0.50$, $P < .001$). An automated immunoassay was performed with an AutoDELFIA 1235 (Wallac) and produced median values of PSP-94 in 205 young men that were 12 mg/L (2.5th to 97.5th percentile, 4.9 to 26 mg/L) in serum and 0.53 g/L (2.5th to 97.5th percentile, 0.13 to 2.0 g/L) or 1.8 mg (2.5th to 97.5th percentile, 0.32 to 6.6 mg) in seminal plasma. These data provide a solid basis for evaluation of this biomarker in healthy men and in those with prostate cancer.

One of the main biologic functions of PSP-94 is the inhibition of follicle-stimulating hormone (Garde et al., 1999). Whereas follicle-stimulating hormone is made by the pituitary gland, the prostate has been shown to be an extrapituitary source of follicle-stimulating hormone. There are follicle-stimulating hormone receptors in the prostate, and it appears that an autocrine or paracrine regulation of this hormone influences prostate epithelial proliferation (Ben-Josef et al., 1999; Porter et al., 2001). Also, Chan et al. (1999) used in situ hybridization to study expression of PSP-94 in human prostates. They found that fetal prostate at 6 to 7 months synthesizes PSA and PAP but not PSP-94, and this observation appears to relate to the development of the prostate gland. Zonal anatomic distribution of PSP-94 in the adult prostate demonstrated that the protein is expressed mostly in the acini of the peripheral zone rather than the central or transitional zones. Anahi Franchi et al. (2008) studied the PSP-94 and its potential interaction with human spermatozoa and its possible role in fertility. Using purified PSP-94, they demonstrated a specific interaction at the sperm surface. Also, using dual-antibody ELISA technology, the authors noted that of 62 patients being assessed for fertility, fertile men had a lower concentration of the protein than subfertile men and suggested that semen quality may be affected by the concentrations of PSP-94. **Another function of PSP-94 may be to interact directly with spermatozoa in a manner that can affect the quality of sperm structure and function.**

In the area of cancer, Chan et al. (1999) found that PSP-94 expression is markedly downregulated with increasing Gleason grade of prostate cancer. Furthermore, Shukeir et al. (2003) demonstrated a significant decrease in growth of the highly metastatic Dunning R3327 subline MatLyLu rat prostate model transfected with parathyroid hormone–related protein by treatment with varying doses of commercial PSP-94 purified from human seminal plasma (0, 0.1, 1.0, and 10 µg/kg/day). Serum levels of parathyroid hormone–related protein and calcium were used to monitor the efficacy of treatment with PSP-94. **Therefore PSP-94 is an effective inhibitor of hormone-independent, late-stage prostate cancer metastasis in this Dunning MatLyLu animal model.** The PSP-94 molecule has not yet been crystallized; however, Joshi and Jyothi (2002), in a computer-simulated molecular model, have predicted its structure and calculated its binding activity and related biologic activity (follicle-stimulating hormone inhibition) and immunogenic properties. Using a three-dimensional structure constructed by nuclear magnetic resonance (NMR), Ghasriani et al. (2006, 2009) have shown the PSP-94 molecule to consist of two distinct domains that form a rather extended structure. The two domains are connected to each other by the peptide backbone, one disulfide bond, and interactions between the amino and carboxyl termini and are oriented to give the molecule a rather extended structure. In addition, Ghasriani et al. (2009) have demonstrated the specific molecular interactions of the PSP-94 with cysteine-rich secretory protein 3 (CRISP-3) by applying multidimensional NMR. The CRISP proteins are ubiquitous among organisms and snake venoms, and they are reported to be calcium ion channel blockers; however, the relevance of these observations of protein-protein interactions to seminal plasma is yet to be determined.

Protein C Inhibitor.

Human semen contains several enzymes and inhibitors of the hemostatic coagulation system (Fernandez and Heeb, 2007; Lwaleed et al., 2004). In human semen, PSA exists as a molecular complex with protein C inhibitor (PCI), and the latter provides some inhibitory consequences for actions of PSA. The predominant structural proteins of coagulated semen are those proteins secreted by the seminal vesicle, including semenogelins I and II and fibronectin, and these proteins remain stable in the seminal vesicle's secretions for up to 20 hours at 37°C but rapidly cleave into small peptides on mixing with the proteases (e.g., PAP, hKLK2 [PSA], hKLK3, hKLK14) of prostatic secretion (Fernandez and Heeb, 2007; Lwaleed et al., 2004). The human PCI gene is located in chromosome 14q32.1 and is a serine protease inhibitor that corresponds to a region containing the genes of related serpins (SERPINA5) (Fernandez and Heeb, 2007; Suzuki et al., 1987, 2007). PCI is a heparin-dependent inhibitor of activated protein C (APC) that is immunologically and functionally identical to a heparin-dependent urokinase inhibitor (plasminogen activator inhibitor type 3). PCI also inhibits several other blood coagulation and fibrinolytic factors (e.g., FXa, FXI, plasma kallikrein) (Espana et al., 2007; Fernandez and Heeb, 2007; Lwaleed et al., 2004; Suzuki et al., 2007). Suzuki et al. (2007) also demonstrated that digestion of human seminal coagula with PSA releases PCI and PSA-PCI complex from the coagula into the soluble phase, suggesting the presence of active PCI within the semen coagula. PCI then forms a “ternary protein complex” with PSA and semenogelin II in the seminal plasma. The binding of semenogelin II to PSA and PCI is influenced by the molecular microenvironment, including pH, ionic strength, heparin, negatively charged dextran sulfate, divalent cations, and particularly by zinc. These observations suggest that binding of PCI to semenogelins in seminal vesicles regulates the PSA-catalyzed degradation of semenogelins in seminal plasma; the complex formation among PCI, PSA, and semenogelins is modulated by several factors in seminal plasma. Espana et al. (2007) determined that PCI is secreted at very high levels in the seminal vesicles in an active form and also occurs in high concentrations in the seminal plasma. The concentration of PCI in 40 seminal plasma samples ranged from 2.2 to 3.7 mM (i.e., about 220 mg/L), and 45% of the seminal PCI was functionally active when assayed immediately after ejaculation. Notably, infertile men had significantly decreased seminal PCI levels (0.6 to 3.2 mM). However, the concentration of PSA in seminal plasma far exceeds the capacity of PCI to inhibit this molecule and hence the biologic role of PCI in seminal plasma. Espana et al. (2007) used purified PCI to assess several functional aspects of PCI, and evidence indicated that PCI is involved in human reproduction at several key steps, including fertilization. Therefore PCI is abundant in the seminal fluid, and it plays a key role in the interaction among semenogelins, PSA, and likely other proteins in semen, resulting in protein-protein interactions critical to semen coagulation and liquefaction. A balance of seminal fluid coagulative proteins, active enzymes, and metabolites is required to effect sperm motility and successful fertilization (Espana et al., 2007; Fernandez and Heeb, 2007; Lwaleed et al., 2004; Suzuki et al., 2007).

Leucine Aminopeptidase.

Aminopeptidases hydrolyze the amino-terminal amino acid from small polypeptides. Leucine aminopeptidases are particularly active against the substrate L-leucyl-glycine, and some of these enzymes are referred to as *arylamidases* because the optimal substrate is L-leucyl-β-naphthylamine. The human prostate is rich in the arylamidase type of leucine aminopeptidase, with a presence in prostatic fluid of 30,000 units/mL.

Leucine aminopeptidase is a product of the epithelial cells of the prostate (Niemi et al., 1963) and is secreted into the lumen of the acini (Kirchheim et al., 1964; Vafa et al., 1993). Rackley et al. (1991) demonstrated that extracts from prostatic carcinoma contained less leucine aminopeptidase activity than did tissue obtained from BPH.

Lactate Dehydrogenase.

The isoenzyme ratios of LDH in human semen may be altered in a patient with prostate cancer (Grayhack et al., 1977; Oliver et al., 1970). LDH (molecular weight 150 kD) is composed of four subunits (each of 35 kD) of only two different types of proteins, denoted M and H. The LDH of muscle has four M units, and that of heart has four H units. Five isoenzymes of LDH can be found in tissues with a four-subunit composition as follows: LDH I, MMMM; LDH II, MMMH; LDH III, MMHH; LDH IV, MHHH; and LDH V, HHHH. The M and H subunits appear to be the same in all tissues, but the amounts of LDH I to V can vary. Denis and Prout (1963) observed increased levels of LDH IV and V in prostate cancer tissue. Several investigators have observed elevated ratios of LDH V/LDH I in human prostate cancer (Elhilali, 1968; Flocks and Schmidt, 1972; Oliver et al., 1970).

Immunoglobulins, C3 Complement, and Transferrin.

There are many reports establishing the presence of Igs in human seminal plasma (Gahankari and Golhar, 1993; Liang et al., 1981). It is possible to measure levels of IgG from 7 to 22 mg/dL and those of IgA from 0 to 6 mg/dL; however, IgM is at low, often undetectable levels (Friberg and Tilley-Friberg, 1976). The complete source of these antibodies is not known, although they are found in expressed prostatic fluid (Grayhack et al., 1979) and may be related to infections (Fowler et al., 1982). They are usually found at lower levels in seminal plasma than in blood, but the possibility of diffusion across the "blood–seminal plasma barrier" has not been eliminated (see discussion by Friberg and Tilley-Friberg, 1976).

Expressed prostatic fluid contains considerable amounts of the C3 component of complement, present at 1.82 mg/dL, and this increases nearly 10-fold in fluid collected from patients with prostatic adenocarcinoma to levels of 16.9 mg/dL (Grayhack and Lee, 1981). Prostatitis has also been shown to be related to C3 in men with chronic prostatitis (Blenk and Hofstetter, 1991). Prostatitis and BPH increase the level only approximately 2-fold. In the same manner, transferrin, an iron-carrying protein, is increased, going from levels of 5.3 mg/dL in normal prostatic fluid to 42.4 mg/dL in prostatic carcinoma (Grayhack and Lee, 1981).

John et al. (2003) conducted a prospective study of the ejaculate of 88 patients with chronic prostatitis by surveying IgG, IgA, and IgM and interleukin-1α, soluble interleukin-2 receptor, and interleukin-6. The control group consisted of 96 normal ejaculates according to the World Health Organization criteria. Ejaculates of patients with chronic prostatitis increased during symptoms and subsided when clinical symptoms decreased. The authors observed that a combination of the humoral immune (IgA and interleukin-6) changes and T-cell–rich infiltrates is suggestive of an autoimmune component of the disease. Alexander et al. (2004) studied a group of patients with chronic granulomatous prostatitis consisting of histologically diffuse nonspecific inflammatory changes that include epithelioid histiocytes and occasional multinucleate giant cells admixed with lymphocytes and plasma cells. They have identified an association between the major histocompatibility locus antigen HLA-DRB2*1501 and granulomatous prostatitis and have suggested the possibility that it may be an autoimmune disease.

Zinc α_2-Glycoprotein.

In the seminal plasma, zinc α_2-glycoprotein (ZAG) is synthesized by PrECs and secreted into seminal fluid (Ding et al., 2007), and it constitutes about 30% of the proteins present in the seminal fluid (Poortmans and Schmid, 1968). The ZAG glycoprotein is found in many body fluids with a molecular mass of 41 kD, and the crystal structure is similar to that of a class I major histocompatibility complex (Burgi and Schmid, 1961; Burgi et al., 1989; Delker et al., 2004; Hassan et al., 2008a, 2008b; Sanchez et al., 1999). In addition, ZAG is assigned to the chromosome 7q22.1 based on fluorescent hybridization karyotyping (Hassan et al., 2008a). The crystal structure of ZAG consists of a large groove analogous to class I major histocompatibility complex peptide-binding grooves, and the structure and environment of the groove reflect its role in immunoregulation and in lipid catabolism (Hassan et al., 2008b; Sanchez et al., 1999). ZAG appears naturally in blood, sweat, **seminal fluid,** breast cyst fluid, cerebrospinal fluid, and urine and is also found in secretory epithelial cells of the liver and the gastrointestinal tract (Hassan et al., 2008a, 2008b; Tada et al., 1991). Biochemically, ZAG stimulates lipid degeneration in adipocytes and appears to be involved in cachexia, a wasting syndrome that can affect people with cancer, acquired immunodeficiency syndrome, and other terminal illnesses (Bing et al., 2004; Hassan et al., 2008b; Hirai et al., 1998; Russell and Tisdale, 2005). The purification and characterization of ZAG from human seminal plasma revealed that it was bound to prolactin-inducible complex (PIP) (Hassan et al., 2008a). With the use of a ZAG tryptic peptide as a standard and a high-flow liquid chromatography–tandem mass spectrometry assay, serum levels in six healthy men were calculated as 3.65 (0.71) mg/L (Bondar et al., 2007). Furthermore, the concentration of ZAG and PIP has been reported to increase dramatically in carcinomas; therefore it has been considered as a good biomarker for prostate, breast, oral, and epidermal carcinomas (Hassan et al., 2008b). Thus **ZAG is a protein regulated by glucocorticoids and has the ability to affect fertilization and lipid mobilization (adipokine).**

Seminal Vesicle Secretory Proteins.

Williams-Ashman (1983) presented a classic review on regulatory features of development and function of the seminal vesicles. The secretory proteins of the seminal vesicles are major proteins and enzymes involved in the rapid clotting of the ejaculate (Cunha et al., 1992). The major clotting protein has been termed *semenogelin* (Lilja and Abrahamsson, 1988). It has been shown to be the seminal vesicle–specific antigen. These clotted proteins from the seminal vesicles serve as substrates for PSA that enzymatically lyse the clot through their protease activity (Aumuller and Seitz, 1990; Lilja, 1985). Beyond the coagulation reaction it is not known what role these seminal vesicle proteins play, but their effects on fertility and uterine sperm motility have been studied in the mouse

(Peitz and Olds-Clarke, 1986). Many of the proteins secreted by the seminal vesicles are under androgen regulation (Hagstrom et al., 1992; Higgins and Hemingway, 1991). More recent work (Harvey et al., 1995) has identified an androgen-regulated protease with elastase-like activity within seminal vesicle secretions. The semenogelins I and II are secreted in abundance by the seminal vesicles. In addition to having coagulum-forming functions and being cleaved by kallikrein-like peptidases to generate biologically active products, the semenogelins are assumed to activate sperm hyaluronidase, affect sperm motility, possess antimicrobial activity, serve as substrates for transglutaminase, and have amyloid properties (de Lamirande, 2007; Hassan et al., 2008b; Jonsson et al., 2006).

In addition, cholesterol and sphingomyelin-rich small, lipid membrane–confined exosome-like vesicles (prostasomes) have been isolated from human semen, and these structures provide an additional source of several hundred proteins that are important to fully understanding the biology of reproduction as well as improving our knowledge of the semen coagulation and liquefaction system (Arienti et al., 1999; Poliakov et al., 2009; Ronquist and Brody, 1985). Prostasomes contain numerous proteins that can affect fertility, promote sperm motility, and stabilize the acrosome reaction (Delves et al., 2007). Sucrose gradient purified prostasomes have been observed by electron microscopy, and their composition has been surveyed after trypsin digestion by liquid chromatography–mass spectroscopy (Poliakov et al., 2009). A diversity of structural and functional proteins involved in fertilization, cell adhesion, apoptosis, immunity, metabolism, signal transduction, transport, angiogenesis, and so on have been identified in prostasomes and have opened a new source of urologic scientific investigation to pursue new biomarkers of disease and elucidate mechanisms of fertility (Delves et al., 2007; Poliakov et al., 2009).

Coagulation and Liquefaction of Semen

Within 5 minutes after ejaculation, human semen coagulates into a semisolid gel. On further standing for a 5- to 20-minute period, the clot spontaneously liquefies to form a viscous liquid (Huggins and Neal, 1942; Mann and Mann, 1981; Tauber and Zaneveld, 1976). Calcium-binding substances, such as sodium citrate and heparin, do not inhibit the coagulation process, nor are prothrombin, fibrinogen, or factor XII required because they are absent in seminal plasma (Mann and Mann, 1981). The seminal clot is formed of fibers 0.15 to 10 nm in width, and its morphologic appearance differs from that of a blood fibrin clot (Huggins and Neal, 1942; Tauber and Zaneveld, 1976; Mann and Mann, 1981). Factors affecting blood coagulation do not regulate semen viscosity (Amelar, 1962). From these observations and others, it appears that the coagulation of human semen is different from that of blood.

Examination of split human ejaculates indicates that the first fraction, originating primarily from the Cowper gland and the prostate, contains the liquefaction factors. The final fraction of the ejaculate, enriched in seminal vesicle secretions, is responsible for the coagulation of the ejaculate (Lilja et al., 1987).

It has long been known that prostatic fluid has a dramatic, fibrinolytic-like activity and that 2 mL of this secretion can liquefy 100 mL of clotted blood in 18 hours at 37°C (Huggins and Neal, 1942; Mann and Mann, 1981). The factors involved in such proteolytic activity in semen have been resolved (Huggins and Neal, 1942; Lilja et al., 1987; Mann and Mann, 1981; Syner et al., 1975; Tauber et al., 1975, 1976; Tauber and Zaneveld, 1976; Zaneveld and Chatterton, 1982). Two types of seminal plasma proteolytic enzymes appear to be major factors in the liquefaction process: plasminogen activators and PSA. Two plasminogen activators have been isolated from seminal plasma; they have molecular weights of 70 and 74 kD and appear to be related to urokinase (Propping et al., 1974). It is believed that the plasminogen activators originate from the prostatic secretions.

The seminal plasma contains a variety of other proteolytic enzymes, including pepsinogen, lysozyme, α-amylase, and hyaluronidase. In addition, human semen inhibits the activity of the proteolytic enzyme trypsin, and this is the result of the presence in the seminal plasma of such proteinase inhibitors as α_1-antitrypsin and α_1-antichymotrypsin. Coagulation and liquefaction vary in different species. For example, the semen of the bull or dog does not coagulate, whereas rodents, such as the rat and guinea pig, ejaculate a firm pellet that does not appear to liquefy (Tauber and Zaneveld, 1976; Tauber et al., 1975, 1976). In rodents the plugs form through the action of an enzyme called *vesiculase*, which comes from the anterior lobe of the prostate and reacts with seminal vesicle secretions. Because of this action, the anterior lobe of the rodent prostate is also called the *coagulating gland*. Vesiculase is not identical to thrombin because it does not coagulate fibrinogen, nor does thrombin clot the secretions of the seminal vesicles. Williams-Ashman et al. (1977) have established that vesiculase has transamidase activity, catalyzing the formation of γ-glutamyl-ε-lysine cross-links in a clottable protein derived from the seminal vesicles. This seminal vesicle protein, which serves as a substrate for vesiculase, is a basic substance with a molecular weight of 17.9 kD; it has been characterized as to its physical properties.

In summary, it appears that seminal plasma coagulation and liquefaction are under enzymatic control, but the biologic purpose of this process has not been resolved. Several key enzymes (e.g., hKLK2 [PSA], hKLK3, hKLK14, PAP) and proteins (e.g., semenogelins, PSP-94, ZAG) of the seminal vesicles and prostate gland are involved in this coagulation and liquefaction system. There have been reports that some infertile men may have impairment of the liquefaction process (Amelar et al., 1977; Anahi Franchi et al., 2008; Bunge, 1970; Bunge and Sherman, 1954; Eliasson, 1973; Jonsson et al., 2006; de Lamirande, 2007; Hassan et al., 2008b; Poliakov et al., 2009).

Key Points: Coagulation and Liquefaction of Semen

- PSA is one of several serine proteases secreted by the prostate in high concentrations into the ejaculate. Although its main function may relate to regulation of semen coagulation, it has proved to be a valuable marker of prostate disease states.
- PCI is abundant in the seminal fluid, and it plays a key role in the interaction among semenogelins, PSA, and likely other proteins in semen, resulting in protein-protein interactions critical to semen coagulation and liquefaction.

Prostatic Secretions and Drug Transport

Aumuller and Seitz (1990) have reviewed the secretory mechanism for the sex accessory tissues. Isaacs (1983) also reviewed the concepts related to the fluid and drug transport properties of the prostate and seminal vesicles and has compared the composition and volume of prostatic secretion under basal stimulation and under neurologic stimulation during ejaculation or pilocarpine stimulation. Isaacs calculated that under neurologic stimulation there is a 205-fold increase in the total potassium, chloride, and sodium output over the basal secretory rate, and he has shown that the prostate is capable of secreting five times its total content of sodium and chloride during this active secretion. These findings show the tremendous transport powers of this system. Smith and Hagopian (1981) have studied the transepithelial voltage changes during prostatic secretion in the dog and have concluded that, although sodium may move passively through the plasma in the prostatic fluid during ejaculation, the movements of potassium and chloride ions involve active transcellular transport. Isaacs et al. (1983) have shown that the androgen-induced secretions can be blocked in the presence of estrogen, although the growth properties and biologic properties of the androgen on the prostate are not markedly altered. This would suggest a direct effect of estrogen in blocking a major transport system in the prostate.

Only a few compounds, including ethanol, iodine, and a few antibiotics, are capable of entering semen by simple diffusion (Reeves, 1982). Drugs entering prostatic secretions have been of interest because of the prevalence of prostatitis and the need for new modalities of chemotherapy. Earlier, Stamey and colleagues had made extensive studies of the ability of chemotherapeutic agents to concentrate in the prostatic fluid of humans and dogs (Hessl and Stamey, 1971; Stamey et al., 1973), and many other investigators have also contributed to this knowledge (Fowler et al., 1982; Madsen et al., 1968, 1976, 1978). Few drugs reach concentrations in the prostatic secretion that approach or surpass their concentrations in blood, but some exceptions are the basic macrolides erythromycin and oleandomycin, sulfonamides, chloramphenicol, tetracycline, clindamycin, trimethoprim, and fluoroquinolones (Reeves, 1982).

In general, these drugs are assumed to pass across the membrane by nonionic diffusion, possibly by lipid solubility, through the membrane; when they reach the more acidic prostatic fluid they are protonated and acquire a more positive charge. Thus the charged drugs become relatively trapped within the prostatic secretions. Several factors are critical, including the pKa of the drug and the pH of the prostatic secretions, as well as the drug binding to proteins in each compartment. Basic drugs would be more positively charged in acidic prostatic fluid than in blood. Slight changes in pH can have large effects on this nonionic diffusion. Samples of prostatic secretions from humans varied widely in pH from 6 to 8, with a mean value of 6.6; however, with prostatic inflammation the pH tended to be 7 or higher (White, 1975). Although prostatic secretions are slightly acidic, the pH of freshly ejaculated human semen is slightly alkaline (pH 7.3 to 7.7); on standing, semen first becomes more alkaline with the loss of carbon dioxide and then later acidic resulting from accumulation of lactic acid. Drugs may be developed in the future that are transported into the prostate as therapeutic agents, as chemoprotectors, or as a route to the semen to regulate fertility; however, more must be learned about the fundamental transport system in and out of the male reproductive tract before such an approach is feasible.

Key Points: Prostatic Secretions and Drug Transport

- Only a few compounds, including ethanol, iodine, and a few antibiotics, are capable of entering the semen by simple diffusion.
- A few exceptions for drugs are the basic macrolides erythromycin and oleandomycin, sulfonamides, chloramphenicol, tetracycline, clindamycin, trimethoprim, and fluoroquinolones. Perhaps these molecules, because of their lipid solubility, are transported by nonionic diffusion.

Benign Prostatic Hyperplasia

Etiology, Pathophysiology, Epidemiology, and Natural History

Claus G. Roehrborn MD, Douglas William Strand PhD

Benign prostatic hyperplasia (BPH) is a pathologic process that is one but certainly not the only cause of lower urinary tract symptoms (LUTS) in aging men—also described as *male LUTS*. Despite intense research efforts in the past five decades to elucidate the underlying etiology of prostatic growth in older men, cause-and-effect relationships have not been established. For example, androgens are necessary, but not sufficient to drive BPH**. Previously held notions that the clinical symptoms of male LUTS (in the past erroneously called *prostatism*) are simply caused by a mass-related increase in urethral resistance are too simplistic.** It is now clear that **a significant portion of male LUTS is caused by age-related detrusor dysfunction and other conditions such as polyuria, sleep disorders, and a variety of systemic medical conditions unrelated to the prostate-bladder unit.**

Historically, voiding symptoms have been related to obstruction of the bladder outlet (Chapple et al., 2008). The traditional association in men is with the prostate, the so-called symptoms of *prostatism*. However, it is well recognized that voiding symptoms poorly correlate with underlying pathophysiology (de la Rosette et al., 1998). Similar symptoms can also be produced by any other form of obstruction, such as a urethral stricture or, conversely, by poor function of the lower urinary tract in circumstances in which there is impaired detrusor contractility. This has led to the recognition that, although LUTS may commonly be related to bladder outlet obstruction (BOO) as a result of benign prostatic obstruction (BPO), which is often associated with benign prostatic enlargement resulting from the histologic condition of BPH, this is not invariably the case.

For example, women also commonly present with voiding symptoms (Irwin et al., 2006). Lepor has shown that age-matched community-dwelling men and women have similar levels of symptom frequency and severity (Lepor and Machi, 1993). Failure to empty can be related either to an outlet obstruction or to detrusor underactivity of the bladder or to a combination of both. Postmicturition symptoms, such as postvoid dribbling, occur in both sexes, but most often in men, in whom these symptoms are highly common, very troublesome, and cause significant interference with quality of life (Reynard et al., 1996). Storage symptoms are currently largely encompassed by the term *overactive bladder (OAB) syndrome*, which is defined as urgency, frequency, nocturia, and urgency incontinence, and which is believed to be correlated with an underlying detrusor overactivity (Abrams et al., 2003). These symptoms tend to be more bothersome than voiding symptoms, especially if they are associated with incontinence. Storage symptoms in both sexes are commonly associated with urinary infections or, more rarely, with other conditions, such as bladder stones, carcinoma, or carcinoma *in situ* in the bladder.

This understanding can be shown as partially overlapping populations (Fig. 144.1). Although many men older than 40 years of age will develop histologic hyperplasia (i.e., BPH), not all will have bothersome LUTS. Of these, some will and others will not develop measurable enlargement of the prostate that may be referred to as *benign prostatic enlargement*, or *BPE*. It is common for men to have BPE without having LUTS and vice versa. BOO may also be present with or without LUTS and with or without BPE, and in some cases, BOO exists in men with BPH (e.g., stricture) (Roehrborn, 2008).

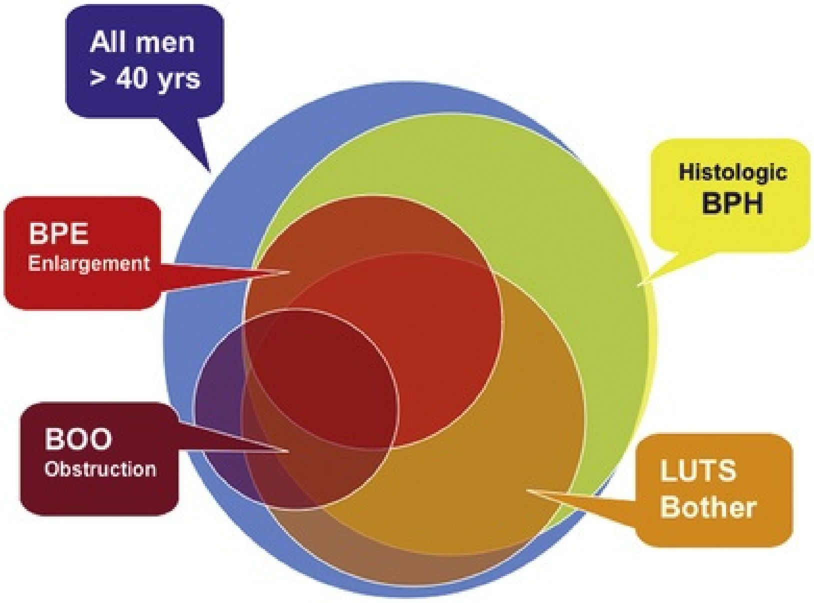

FIG. 144.1 Diagram showing the relationship between histologic hyperplasia of the prostate *(BPH),* lower urinary tract symptoms *(LUTS),* benign prostate enlargement *(BPE),* and bladder outlet obstruction *(BOO).* The size of the circles does not represent actual proportions but rather illustrates the partial overlap between the different disease definitions. (From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 20[Suppl 3]:S11–S18, 2008.)

Undoubtedly, the constellation of cellular pathologies that give rise to the symptoms of LUTS is far more complex than we currently realize. Only by unraveling these complexities, however, will we be able to design alternative strategies to treat successfully and possibly prevent the adverse impact of BPH on lower urinary tract function.

Etiology of Benign Prostatic Hyperplasia

Histopathologically, BPH is characterized by an increased number of epithelial and stromal cells in the periurethral area of the prostate and thus is correctly referred to as *hyperplasia* and not *hypertrophy*, as is often found in the older literature. The observation of new epithelial gland formation is normally seen only in fetal development and gives rise to the concept of embryonic reawakening of the stroma cell's inductive potential (Cunha et al., 1983; Isaacs, 2008). The precise molecular etiology of this hyperplastic process is uncertain. **The observed increase in cell number may be caused by epithelial and stromal proliferation or impaired programmed cell death leading to cellular accumulation.** Androgens, estrogens, stromal-epithelial interactions, growth factors, and neurotransmitters may play a role, either singly or in combination, in the etiology of the hyperplastic process.

Hyperplasia

In a given organ, the number of cells, and thus the volume of the organ, is dependent on the equilibrium between cell proliferation and cell death (Isaacs and Coffey, 1989). An organ can enlarge not only by an increase in cell proliferation but also by a decrease in cell death. **Although androgens and growth factors stimulate cell proliferation in experimental models, the relative role of cell proliferation in human BPH is questioned because there is no clear evidence of an active proliferative process.** Although it is possible that the early phases of BPH are associated with a rapid proliferation of cells, the established disease appears to be maintained in the presence of an equal or reduced rate of cell replication. Increased expression of antiapoptotic pathway genes (e.g., *bcl-2*) supports this hypothesis (Colombel et al., 1998; Kyprianou et al., 1996). **Androgens not only are required for normal cell proliferation and differentiation in the prostate but also actively inhibit cell death** (Isaacs, 1984). In dogs, experimental BPH can be produced by androgens combined with estradiol (Berry et al., 1986a; DeKlerk et al., 1979; Juniewicz et al., 1994; Walsh and Wilson, 1976). Despite a significant increase in gland size, there is actually a reduction in the rate of DNA synthesis compared with untreated controls (Barrack and Berry, 1987), indicating that androgens and estrogens both inhibit the rate of cell death. Neural signaling pathways, especially α-adrenergic pathways, may also play a role in balancing cell death and cell proliferation (Anglin et al., 2002).

Hyperplasia results in a remodeling of the normal prostatic architecture (Untergasser et al., 2005). Epithelial budding from preexisting ducts and the appearance of mesenchymal nodules characterize early stages of the process, but the tissue phenotype of patients with established disease is highly variable (Strand et al., 2017). This phenotypic heterogeneity has likely confounded a precise understanding of the molecular pathogenesis of hyperplasia.

Branching morphogenesis is a developmental process regulated by stromal-epithelial interactions in the fetal prostate (Yu and Bushman, 2013). Castration in an adult mouse results in involution of distal branches; testosterone replacement works through stromal androgen receptor (AR) to induce glandular regeneration (Sugimura et al., 1986a,b).

BPH may be viewed as a stem cell disease (Isaacs, 2008), but the precise identity of these cells has proven elusive. In transgenic mice, lineage tracing using promoters that label basal or luminal epithelia with fluorescent proteins has shown that stem cells within both lineages are capable of contributing to prostate regrowth after inducing forms of stress such as castration, inflammation, obesity, or luminal anoikis (Kwon et al., 2014a, 2016; Toivanen et al., 2016; Wang et al., 2009). In the adult human prostate, quantitative clonal mapping revealed that multipotent basal stem cells in the proximal niche are mainly responsible for replenishing the loss of apoptotic luminal epithelia (Moad et al., 2017).

Presumably, dormant stem cells in the normal prostate rarely divide, but when they do, they give rise to a second type of transiently proliferating cell capable of undergoing DNA synthesis and proliferation, thus maintaining the number of cells in the prostate. When the proliferating cells mature through a process of terminal differentiation, they have a finite life span before undergoing programmed cell death. In this paradigm, **the aging process induces a block in this maturation process so that the progression to terminally differentiated cells is reduced, reducing the overall rate of cell death.** Indirect evidence for this hypothesis comes from the observation that secretion, one parameter of epithelial cell differentiation, decreases with age, suggesting that the number of differentiated cells capable of secretory activity may be decreasing (Isaacs and Coffey, 1989). In humans, PSA expression in luminal epithelia decreases with increasing prostate volume (Zhang et al., 2016). A survey of human BPH specimens for a marker of cellular senescence (senescence-associated βgalactosidase [SA-beta-gal]) demonstrated a higher portion of senescent epithelial cells in men with large prostates, suggesting that an accumulation of these cells may play a role in the development of prostate enlargement (Choi et al., 2000). More recent studies support the hypothesis that impaired cell senescence may play a significant role in the etiology of BPH (Castro et al., 2003).

Hormones may exert their influence over the stem cell population not only with advancing age but also during embryonic and neonatal development (Naslund and Coffey, 1986). The size of the prostate may be defined by the absolute number of potential stem cells present in the gland, which in turn may be dictated at the time of embryonic development. Studies in animal models have suggested that **early imprinting of prostatic tissue by postnatal androgen surges is critical to subsequent hormonally induced prostatic growth.** As with the hormonal regulation of adult prostatic tissues, sex steroid hormones may exert their imprinting effect directly or indirectly through a complex series of signaling pathways (Lee and Peehl, 2004).

The Role of Androgens

Although androgens do not cause BPH, the development of BPH requires the presence of testicular androgens during prostate development, puberty, and aging (Marcelli and Cunningham, 1999; McConnell, 1995). Patients who are castrated before puberty or who are affected by a variety of genetic diseases that impair androgen action or production do not develop BPH. It is also known that prostatic levels of dihydrotestosterone (DHT) and the AR remain high with aging despite the fact that peripheral levels of testosterone are decreasing. Moreover, androgen withdrawal leads to partial involution of established BPH (Isaacs, 2008; Peters and Walsh, 1987).

Assuming normal ranges, there is no clear relationship between the concentration of circulating androgens and prostate size in aging men. In the Olmsted County cohort (median age 60.9) serum bioavailable testosterone levels were found to decline with increasing age, and the estradiol/bioavailable testosterone ratio increased (Roberts et al., 2004). Bioavailable testosterone correlated negatively and estradiol/bioavailable testosterone ratio positively with prostate volume, but this association was much less apparent after age adjustment. Baseline data from a large BPH medical therapy study confirmed the absence of a relationship among serum testosterone, serum PSA, and prostate volume (Marberger et al., 2006) (Table 144.1). On the other hand, in a 20-year follow-up study, Parsons et al showed that higher baseline serum dihydrotestosterone levels were associated with an increased risk for BPH. The odds ratios (OR) for the second, third, and fourth quartiles of dihydrotestosterone were 1.83 (95% CI, 0.96 to 3.47), 1.50 (0.79 to 2.85), and 2.75 (1.46 to 5.19), respectively (p trend = 0.02). A higher testosterone-to-dihydrotestosterone ratio, however, was associated with a 42% decreased risk for BPH (Parsons et al., 2010; Trifiro et al., 2010).

Modified from Marberger M, Roehrborn CG, Marks LS, et al. Relationship among serum testosterone, sexual function, and response to treatment in men receiving dutasteride for benign prostatic hyperplasia. *J Clin Endocrinol Metab* 91(4):1323–1328, 2006.

In the brain, skeletal muscle, and seminiferous epithelium, testosterone directly stimulates androgen-dependent processes. **In the prostate, however, the nuclear membrane bound enzyme steroid 5α-reductase converts the hormone testosterone into DHT, the principal androgen in this tissue (see Fig. 144.1)** (McConnell, 1995). Ninety percent of total prostatic androgen is in the form of DHT, principally derived from testicular androgens. Adrenal androgens may constitute 10% of total prostatic androgen, although the importance of this stored hormone source in the etiology of BPH is negligible.

Inside the cell, both testosterone and DHT bind to the same high-affinity androgen receptor protein (Chatterjee, 2003). DHT is a more potent androgen than testosterone because of its higher affinity for the AR. Moreover, the DHT-receptor complex may be more stable than the testosterone-receptor complex. The hormone receptor then binds to specific DNA-binding sites in the nucleus, which results in increased transcription of androgen-dependent genes and ultimately stimulation of protein synthesis (Andriole et al., 2004). Conversely, androgen withdrawal from androgen-sensitive tissue results in a decrease in protein synthesis and tissue involution. **Besides inactivation of key androgen-dependent genes (e.g., prostate-specific antigen [PSA]), androgen withdrawal leads to the activation of specific genes involved in programmed cell death** (Kyprianou and Isaacs, 1989; Martikainen et al., 1990). Despite the importance of androgens in normal prostatic development and secretory physiology, there is no evidence that either testosterone or DHT serves as the direct mitogen for growth of the prostate in older men. Indeed, neither hormone is mitogenic to cultured prostatic epithelial cells (McKeehan et al., 1984). In the rat ventral prostate, differential gene expression experiments failed to demonstrate direct activation of mitogenic pathways (Wang et al., 1997). However, many proinflammatory cytokines as well as growth factors and their receptors are regulated by androgens (see later). Thus, the action of testosterone and DHT in the prostate is mediated indirectly through autocrine and paracrine pathways.

Androgen Receptors

The prostate, unlike other androgen-dependent organs, maintains its ability to respond to androgens throughout life. In the penis, AR expression decreases to negligible rates at the completion of puberty (Roehrborn et al., 1987; Takane et al., 1991a,b). Thus, despite high circulating levels of androgen, the adult penis loses its ability for androgen-dependent growth. If the penis maintained high levels of AR throughout life, presumably the organ would grow until the time of death. In contrast, AR levels in the prostate remain high throughout aging (Barrack et al., 1983; Rennie et al., 1988). In fact, there is evidence to suggest that nuclear AR levels may be higher in hyperplastic tissue than in normal controls. Age-related increases in estrogen, as well as other factors, may increase AR expression in the aging prostate, leading to further growth (or to a decrease in cell death), despite decreasing levels of androgen in the peripheral circulation and “normal” levels of DHT in the prostate.

The potential roles of AR mutations, polymorphisms, or other alterations in the pathogenesis of BPH are unclear (Chatterjee, 2003). A polymorphism in the number of CAG repeats (short vs. control) in the *AR* gene has been associated with larger prostate size and an increased risk for surgery (Giovannucci et al., 1999a,b). However, another study from the Netherlands showed no relationship between the number of CAG repeats and BPH (Bousema et al., 2000). The later study also found no relationship between BPH and vitamin D receptor polymorphisms, although one Japanese study suggested an association (Habuchi et al., 2000b). A more recent study of US men showed a positive correlation between short CAG repeats and prostate volume, but a study of Finnish men found that short CAG repeats were significantly less common in men with BPH compared with control subjects (Mononen et al., 2002). Given the significant variation in reported findings, if short CAG repeats play a role in BPH pathogenesis, it is likely to be minor (Hoke and McWilliams, 2008).

Dihydrotestosterone and Steroid 5α-Reductase

Intraprostatic DHT concentrations are maintained but not elevated in BPH. Initial studies of resected prostatic tissue suggested that prostatic DHT levels were higher in the hyperplastic gland than in normal control tissues. However, the controls used for these early studies were largely accident victims. Ongoing metabolism of DHT after death lowers the level of this androgen in cadaveric tissues. This was clearly shown in a study by Walsh et al. (1983) in which prostatic surgical specimens from men without BPH were used as the control. These investigators demonstrated that DHT levels are the same in hyperplastic glands as in normal glands. However, the aging prostate maintains a high level of DHT and a high level of AR; thus, the mechanism for androgen-dependent cell growth is maintained. There is little question that androgens have at least a permissive role in the development of the disease process.

Two steroid 5α-reductase enzymes have been discovered, each encoded by a separate gene (Russell and Wilson, 1994). Type 1 5α-reductase, the predominant enzyme in extraprostatic tissues, such as skin and liver, is normally expressed in the 5α-reductase deficiency syndrome and is inhibited by dutasteride, but not substantially by finasteride. Type 2 5α-reductase is the predominant prostatic 5α-reductase, although it is also expressed in extraprostatic tissues. Mutations in the type 2 enzyme are responsible for the clinical phenotype observed in the 5α-reductase deficiency syndrome. It is exquisitely sensitive to inhibition by finasteride and dutasteride (Carson and

Rittmaster, 2003). Clearly, **the type 2 enzyme is critical to normal development of the prostate and hyperplastic growth later in life.** The role of type 1 5α-reductase in normal, and abnormal prostate growth remains to be defined. There is growing evidence to suggest that the type 1 isoenzyme may play a more important role in prostate cancer compared with BPH, as increased levels of mRNA expression, protein, and functional enzymes have been demonstrated in prostate cancer (Thomas et al., 2008). Given that finasteride produces prostate size reduction identical to that with dual type1/type 2 inhibitors and roughly equivalent to that with castration, it is unlikely that type 1–derived DHT is critical to hyperplastic growth.

Immunohistochemical studies with type 2 5α-reductase–specific antibodies show primarily stromal cell localization of the enzyme (Silver et al., 1994; Thigpen et al., 1993). Epithelial cells uniformly lack type 2 protein, and some basal epithelial cells stain positively. Type 1 5α-reductase protein could not be detected in BPH or prostate cancer using initially available antibodies, although trace levels of type 1 messenger RNA (mRNA) have been seen in normal prostates, BPH, and cancer (Shirakawa et al., 2004). A study with a selective type 1 antibody demonstrated positive staining in only 7% of BPH cases (Thomas et al., 2003). In the same study, type 1 enzymatic activity was found in only 2 of 29 BPH specimens.

These data demonstrate that the **stromal cell plays a central role in androgen-dependent prostatic growth and that the type 2 5α-reductase enzyme within the stromal cell is the key androgenic amplification step.** Thus, a paracrine model for androgen action in the gland (Fig. 144.2) is evident. In addition, it is possible that **circulating DHT produced in the skin and liver may act on prostate epithelial cells in a true endocrine fashion** (McConnell, 1995). If dual type 1/type 2 5α-reductase inhibition has clinical utility over selective type 2 inhibitors, it is likely to be caused by inhibition of peripherally produced DHT.

FIG. 144.2 Testosterone *(T)* diffuses into the prostate epithelial and stromal cell. Testosterone can interact directly with the androgen (steroid) receptors bound to the promoter region of androgen-regulated genes. In the stromal cell, a majority of testosterone is converted into dihydrotestosterone (DHT)—a much more potent androgen—which can act in an autocrine fashion in the stromal cell or in a paracrine fashion by diffusing into epithelial cells in close proximity. DHT produced peripherally, primarily in the skin and liver, can diffuse into the prostate from the circulation and act in a true endocrine fashion. In some cases, the basal cell in the prostate may serve as a DHT production site, similar to the stromal cell. Autocrine and paracrine growth factors may also be involved in androgen-dependent processes within the prostate. (From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 20[Suppl 3]:S11–S18, 2008.)

Immunohistochemical studies in open enucleated BPH specimens show considerable intraprostatic and interprostatic 5α-reductase enzyme expression, making studies of its distribution based on single or one-time biopsy material very difficult (Sherwood et al., 2003). Because it is the only medical treatment available for reducing prostate volume, defining the resistance to 5ARI treatment is an important scientific question although complex. Clinically, 5ARI resistance may be defined as failure to significantly improve LUTS, but this is unlikely to be caused by failure of the drug to reduce intraprostatic DHT levels (personal observation). More likely, clinical failure is caused by (1) a lack a luminal epithelial atrophy focally within glandular nodules resulting in persistent anatomic obstruction, or (2) widespread stromal hyperplasia (Strand et al., 2017).

Several mechanisms have been proposed for mediating the resistance of luminal epithelia to 5ARI treatment. Austin et al. (2016a,b) showed in human tissue and cell lines that NF-κB is increased in BPH and could induce expression of androgen-independent AR variant expression. Wang et al. (2017) demonstrated that SRD5A2 can be epigenetically silenced in a subset of BPH patients, resulting in a switch to estrogenic pathways for survival. Interestingly, both of these mechanisms are linked to inflammation, and inflammation is also correlated with 5ARI resistance in clinical trials (Nickel et al., 2008). However, these pathways are still correlative and have yet to be proven responsible for 5ARI resistance in vivo. A clinical definition of resistance should include volumetric (prostate volume unchanged), histologic (lack of glandular atrophy), and biochemical (decreased DHT) criteria.

Polymorphisms in the type 2 5α-reductase enzyme (SRD5A2) have been reported, but their linkage to BPH is uncertain. The *SRD5A2* gene on chromosome 2p23 frequently encompasses A49T and V89L substitutions and a TA dinucleotide repeat polymorphism. The *89L* allele has been associated with lower enzyme activity, whereas the *49T* allele has been associated with higher activity. Longer TA repeats are associated with mRNA instability and thus decreased enzyme activity. The number of *L* alleles, but not testosterone alleles or TA repeats, in one study correlated significantly with the presence of BPH (Salam et al., 2005). In the Olmsted County population, consistent associations between SRD5A2 genotypes and BPH were not demonstrated, although there was a weak correlation between V89L polymorphisms and prostate volume (Roberts et al., 2005).

Androgen withdrawal may partially exert its effect on the prostate through vascular effects (Buttyan et al., 2000). Castration induces acute and drastic vasoconstriction of blood vessels in the rat prostate (Hayek et al., 1999). This effect does not appear to be mediated through vascular endothelial growth factor (VEGF) (Burchardt et al., 2000). There is indirect evidence to suggest that abnormalities in the prostatic vascular system produced by other disease states (e.g., diabetes) may be a risk factor of BPH (Parsons, 2007; Parsons et al., 2006).

The Role of Estrogens

There is animal model evidence to suggest that estrogens play a role in the pathogenesis of BPH; the role of estrogens in the development of human BPH, however, is less clear. In the dog, where estrogens act synergistically with androgens to produce experimental BPH, estrogen appears to be involved in induction of the AR (Moore et al., 1979). Estrogen may, in fact, "sensitize" the aging dog prostate to the effects of androgen (Barrack and Berry, 1987). The canine prostate contains an abundance of high-affinity estrogen receptor. In the dog, estrogen treatment stimulates the stroma, causing an increase in the total amount of collagen (Berry et al., 1986a, 1986b). There are at least two forms of the estrogen receptor. Estrogen receptor α is expressed by prostate stromal cells, and estrogen receptor β is expressed by prostate epithelial cells (Prins et al., 1998). The estrogenic response of the prostate is determined by the type of estrogen receptor present within the prostatic cells. Experiments in knockout mice suggest a "constraining influence" of estrogens on the prostate (Krege et al., 1998). In vitro studies suggest that upregulation of estrogen receptor α in cultured prostate stromal cells is also associated with upregulation of fibroblast growth factor 2 (FGF-2), FGF-7, and other growth factors; the addition of androgens downregulated the estrogen receptor and various stroma-derived growth factors (Smith et al., 2000, 2002).

Different actions may be mediated by stromal ERα and epithelial ERβ (Prins and Korach, 2008). Evidence also indicates that estrogen action mediated through the separate receptors may contribute to the etiology and progression of multiple prostate diseased states (Table 144.2). These findings provide new avenues and alternative approaches for the treatment of prostate diseases, including prostate cancer, with novel therapies directed at estrogen receptors or estrogen metabolism. Because the two types of estrogen receptors may play distinct and perhaps opposing roles in many diseases of the prostate including cancer progression, it is possible that receptor-specific agonists and antagonists may prove beneficial in therapeutic strategies in future clinical trials. A recent randomized, placebo-controlled study using an ERβ agonist in men with male LUTS failed, however, to show any effect on symptoms, serum PSA, prostate size, and urodynamic parameters (Roehrborn et al., 2015).

Serum estrogen levels increase in men with age, absolutely or relative to testosterone levels. There is also suggestive evidence that intraprostatic levels of estrogen are increased in men with BPH. Patients with larger volumes of BPH tend to have higher levels of estradiol in the peripheral circulation (Partin et al., 1991). In the Olmsted County cohort, in men with above median levels of bioavailable testosterone, serum estradiol level correlated positively with prostate volume, even after adjusting for age (Roberts et al., 2004). Data on obesity, serum testosterone, estradiol, and prostate volume are conflicting (Zucchetto et al., 2005). Although there are relatively low concentrations of classical high-affinity estrogen receptors in human BPH (Farnsworth, 1996; Sciarra and Toscano, 2000), there may be a sufficient amount for biologic activity.

From experimental studies with aromatase inhibitors, it appears that decreases in intraprostatic estrogen in animal models may lead to reduction in drug-induced stromal hyperplasia (Farnsworth, 1996, 1999). At present, however, the role of estrogens in human BPH is not as firmly established as the role of androgens. Species variation and cause-and-effect relationships are problematic.

There are high levels of progesterone receptor in the normal and hyperplastic prostate. However, the role of the progesterone receptor in normal prostatic physiology and in BPH remains to be defined.

Regulation of Programmed Cell Death

Programmed cell death (apoptosis) is a physiologic mechanism crucial to the maintenance of normal glandular homeostasis (Kerr and Searle, 1973). Cellular condensation and fragmentation precede phagocytosis and degradation, during which the apoptotic cell is phagocytosed by neighboring cells and degraded by lysosomal enzymes. Apoptosis occurs without activation of the immune system but requires both RNA and protein synthesis (Lee, 1981). In the rat prostate, active cell death occurs naturally in the proximal segment of the prostatic ductal system in the presence of normal concentrations of plasma testosterone (Lee et al., 1990). Androgens (presumably testosterone and DHT) appear to suppress programmed cell death elsewhere in the gland. **Following castration, active cell death is increased in the luminal epithelial population and in the distal region of each duct.** Tenniswood suggested that there is regional control over androgen action and epithelial response, with androgens providing a modulating influence over the local production of growth regulatory factors that varies in different parts of the gland (Tenniswood, 1986). Members of the transforming growth factor β (TGF-β) family are likely candidates for this regulatory step (Martikainen et al., 1990).

In the rat prostate, at least 25 different genes are induced after castration (Montpetit et al., 1986). Normal glandular homeostasis requires a balance between growth inhibitors and mitogens, which respectively restrain or induce cell proliferation but also prevent or modulate cell death. Abnormal hyperplastic growth patterns, such as BPH, might be induced by local growth factor or growth factor receptor abnormalities, leading to increased proliferation or decreased levels of programmed cell death.

Stromal-Epithelial Interaction

There is abundant experimental evidence to demonstrate that **prostatic stromal and epithelial cells maintain a sophisticated paracrine type of communication.** The growth of canine prostate epithelium can be regulated by cellular interaction with the basement membrane and stromal cells. Isaacs and Coffey used a marker of canine prostatic epithelial cell function to demonstrate that epithelial cells grown on plastic quickly lose their ability to secrete this protein (Isaacs and Coffey, 1989). In addition, the cells begin to grow rapidly and change their cytoskeletal staining pattern. In contrast, if the cells are grown on prostatic collagen, they maintain their normal secretory capacity and cytoskeletal staining pattern and do not grow rapidly. This is strong evidence that

one class of stromal cell excretory protein (i.e., extracellular matrix) partially regulates epithelial cell differentiation. Thus, BPH may be caused by a defect in a stromal component that normally inhibits cell proliferation, resulting in loss of a normal "braking" mechanism for proliferation. This abnormality could act in an autocrine fashion to lead to proliferation of stromal cells as well.

Further evidence of the importance of stromal-epithelial interactions in the prostate comes from the elegant developmental studies of Cunha, which demonstrate the importance of embryonic prostatic mesenchyme in dictating differentiation of the urogenital sinus epithelium (Cunha et al., 1980, 1983, 2003; Cunha and Donjacour, 1987; Cunha, 1994). **The process of new gland formation in the hyperplastic prostate suggests a "reawakening" of embryonic processes in which the underlying prostatic stroma induces epithelial cell development (McNeal, 1990).** Many of the prostatic stromal-epithelial interactions observed during normal development and in BPH may be mediated by soluble growth factors or by the extracellular matrix (ECM), which itself has growth factor–like properties. This model is even more intriguing, given the cellular localization of 5α-reductase (and thus DHT production) in the prostate stromal cell (Silver et al., 1994).

The complexity of the stromal-ECM-epithelial relationship is revealed in studies of CXC motif chemokines such as CXCL1, CXCL5, CXCL6, and CXCL12. These chemokines are predominantly expressed by the microenvironment, but are capable of stimulating proliferation of both stroma and epithelia in vitro. Furthermore, these chemokines and others such as interleukin (IL)-8 are capable of converting fibroblasts to myofibroblasts (Schauer et al., 2008). Myofibroblasts are associated with increased collagen deposition and fibrosis, potentially contributing to lower urinary tract dysfunction (Rodriguez-Nieves and Macoska, 2013).

As described in many other organs, there is a putative stem cell niche in the prostate that is composed of a set of poorly defined stromal and epithelial cell types. Several signaling pathways including Hedgehog (Karhadkar et al., 2004; Wang et al., 2003), Notch (Wang et al., 2004; Wu et al., 2011), WNT (Murillo-Garzon and Kypta, 2017), and TGFβ (Salm et al., 2012) are implicated in the autocrine/paracrine maintenance of the stem cell niche. As our understanding of stromal-epithelial cell relationships in the prostate increases, it is possible that therapies may be designed to induce regression of established BPH by modulating these autocrine/paracrine mechanisms.

Growth Factors

Growth factors are small peptide molecules that stimulate, or in some cases inhibit, cell division and differentiation processes (Lee and Peehl, 2004; Steiner, 1995). Cells that respond to growth factors have on their surface receptors specific for that growth factor that in turn are linked to a variety of transmembrane and intracellular signaling mechanisms. **Interactions between growth factors and steroid hormones may alter the balance of cell proliferation versus cell death to produce BPH** (Fig. 144.3). Story et al. (1989) were first to demonstrate that extracts of BPH stimulate cellular growth. This putative prostatic growth factor was subsequently found on sequence analysis to be basic fibroblastic growth factor (bFGF). Subsequently, a variety of growth factors have been characterized in normal, hyperplastic, and neoplastic prostatic tissue. In addition to bFGF (FGF-2), acidic FGF (FGF-1), Int-2 (FGF-3), keratinocyte growth factor (KGF, FGF-7), transforming growth factor (TGF-β), and epidermal growth factor (EGF) have been implicated in prostate growth. TGF-β is a potent inhibitor of proliferation in normal epithelial cells in a variety of tissues. In models of prostatic cancer, there is evidence that malignant cells have escaped the growth inhibitory effect of TGF-β (McKeehan and Adams, 1988). Similar mechanisms may be operational in BPH (Salm et al., 2000), leading to the accumulation of epithelial cells (Kundu et al., 2000). Growth factors may also be important in modulating the phenotype of the prostate smooth muscle cell (Peehl and Sellers, 1998).

Prostate hyperplasia

FIG. 144.3 Prostate hyperplasia is most likely due to an imbalance between cell proliferation and cell death. Androgens play a necessary but probably permissive role. Growth factors are more likely to be sites of primary defects.

There is mounting evidence of interdependence between growth factors, growth factor receptors, and the steroid hormone milieu of the prostate (Lee and Peehl, 2004; Rennie et al., 1988). Although data on the absolute level of growth factor and growth factor receptors in hyperplastic as opposed to normal tissue are conflicting, it is likely that growth factors play some role in the pathogenesis of BPH. However, further research is necessary to establish the role of growth factors in a disease process in which cellular proliferation is not obvious.

If cellular proliferation is a component of the BPH process, it appears that growth stimulatory factors such as the FGF-1, -2, -7, and -17 families; VEGF; and insulin-like growth factor (IGF) may play a role, with DHT augmenting or modulating the growth factor effects. In contrast, TGF-β, which is known to inhibit epithelial cell proliferation, may normally exert a restraining influence over epithelial proliferation that is lost or downregulated in BPH (Cohen et al., 2000; Lee and Peehl, 2004; Peehl et al., 1995; Sporn and Roberts, 1990; Wilding et al., 1989). TGF-β_1 is a potent mitogen for fibroblasts and other mesenchymal cells but is also an important inhibitor of epithelial cell proliferation (Roberts and Sporn, 1993). TGF-β_1 also regulates ECM synthesis and degradation and can induce cells to undergo apoptosis. In addition, TGF-β upregulates the production of basic fibroblast growth factor (bFGF-2), which is known to be an autocrine growth factor for prostate stromal cells (Story et al., 1993), and at least on one prostate smooth muscle cell line (PSMC1), TGF-β1 functions as an autocrine mitogen (Salm et al., 2000). Thus, upregulation of TGF-β1 (which is expressed in prostate stromal cells) during BPH would favor expansion of the stromal compartment.

Indirect evidence to support this view comes from studies of reconstituted mouse prostate (Yang et al., 1997). Interestingly, the observation that TGF-β1 may regulate smooth muscle contractile protein expression suggests that TGF-β isoforms may be physiologic regulators of prostatic smooth muscle function (Orlandi et al., 1994). Cohen et al. (2000) found that stromal cells isolated from BPH specimens exhibited a blunted TGF-β growth inhibition relative to normal stromal cells and that the blunted response appeared to be caused by a reduction in TGF-β–mediated increase in IGF-binding protein 3 (IGFBP-3) expression. TGF- β may stimulate the overexpression of versican (chondroitin sulfate proteoglycan 2) in the ECM through inhibition of key metalloproteases (ADAMTS lineage) that normally degrade versican, leading to accumulation in the ECM (Cross et al., 2006). An increased risk for BPH was described in patients with a codon 10 polymorphism in TGF-β (Li et al., 2004).

The first evidence of increased FGF-2 levels in BPH came from the studies of Begun et al. (1995), who demonstrated a twofold to threefold elevation of FGF-2 in BPH compared with histologically normal glands. Further studies have demonstrated that both FGF-2 and FGF-7 are overexpressed in BPH tissues (Ropiquet et al., 1999). The major target of FGF-2 is thought to be the stroma itself (autocrine), although transgenic mice overexpressing FGF-2 develop glandular epithelial hyperplasia (Konno-Takahashi et al., 2004). KGF, a member of the FGF family (FGF-7), is produced in prostatic stromal cells (Yan et al., 1992). However, cell surface receptors for stroma-derived KGF are expressed exclusively in epithelial cells. As a result, **FGF-7 (or a homolog) is the leading candidate for the factor mediating the stromal cell–based hormonal regulation of the prostatic epithelium.** There is direct evidence that FGF-7 plays this role in the androgen-dependent mesenchymal-epithelial interactions involved in development of the seminal vesicle (Alarid et al., 1994). Abnormalities in stromal FGF-7 production or epithelial FGF-7 receptor could promote epithelial cell proliferation. Indirect evidence supporting this hypothesis comes from a study of transgenic mice overexpressing FGF-7 that develop atypical prostatic hyperplasia (Kitsberg and Leder, 1996). McKeehan's laboratory demonstrated that FGF-10, a homolog of FGF-7, is expressed at high levels in the rat prostate, specifically in stromal cells of smooth muscle origin (Lu et al., 1999; Nakano et al., 1999). FGF-10 expression is increased by androgens and may have a mitogenic effect on prostate epithelium. Other studies suggest that cells expressing FGF-7 are localized in the stroma immediately adjacent to the epithelium, suggesting that the epithelial cells may induce FGF-7 expression. The paracrine factor most likely responsible for this effect is cytokine interleukin (IL)-1a (Giri and Ittmann, 2000; Lee and Peehl, 2004).

Some investigators have speculated that local hypoxia in the prostate (perhaps from atherosclerosis or other vascular events) is the initial event that induces FGF production (Lee and Peehl, 2004). Further growth of BPH nodules could impede blood flow, leading to further hypoxia (Parsons and Kashefi, 2008; Parsons et al., 2008). Hypoxia leads to upregulation of hypoxia inducible factor 1, which in turn increases the secretion of FGF-2 and FGF-7 from stromal cells.

Other growth factors implicated in BPH include FGF-17 (Polnaszek et al., 2004), FGF-10, and VEGF (Walsh et al., 2002). It remains difficult to ascertain which of the growth factors and growth factor receptors are key mediators of the BPH disease process and which are bystanders.

Insulin-like growth factors, binding proteins, and receptors also appear to be important modulators of prostatic growth, at least as it relates to cell growth in culture (Lee and Peehl, 2004; Peehl et al., 1995). A transgenic mouse model with overexpression of IGF-1 demonstrated prostate gland enlargement (Konno-Takahashi et al., 2003). Studies of BPH tissue demonstrate a higher concentration of IGF-2 in the periurethral area than in the peripheral zone (Monti et al., 2001). A study of Chinese men demonstrated a significant correlation between circulating IGF-1 and IGFBP-3 level and BPH (Dahle et al., 2002), but a study of the Olmsted County cohort failed to demonstrate any relationship between serum IGF-1 and prostate volume (Roberts et al., 2003).

Other Signaling Pathways

Sympathetic signaling pathways are important in the pathophysiology of LUTS, as is evident from the use of drugs interfering with the adrenergic nervous system such as α-adrenergic receptor blockers, which are highly effective for the treatment of LUTS (American Urological Association Practice Guidelines Committee, 2003). In addition, there is increasing evidence that sympathetic pathways may be important in the pathogenesis of the hyperplastic growth process (McVary et al., 1994, 2005). Alpha blockade, in some model systems, can induce apoptosis (Anglin et al., 2002). α-Adrenergic pathways can also modulate the smooth muscle cell phenotype in the prostate (Lin et al., 2000). All components of the renin-angiotensin system (RAS) are present in prostatic tissue and may be activated in BPH (Dinh et al., 2001, 2002; Fabiani et al., 2001). Either with or without sympathetic modulation, local RAS pathways may contribute to cell proliferation and smooth muscle contraction.

The early growth response gene 1 *(EGR-1)* transcription regulation pathway was found to be active in a BPH cell line (Mora et al., 2005). Also of interest is the finding that α_2-macroglobulin, a large protein that binds PSA and many growth factors, is very highly expressed in human prostate and is upregulated in BPH (Lin et al., 2005). Trapping and inactivation of inhibitory molecules could promote growth pathways.

The Potential Role of Inflammatory Pathways and Cytokines in Benign Prostatic Hyperplasia

An additional source of growth factors in human BPH tissue may be the inflammatory cell infiltrates seen in many men with BPH. In the 1990s, descriptive studies suggested a link between inflammation and BPH-related growth. Theyer et al. (1992) reported extensive infiltration of human BPH tissues by activated T cells. Peripheral blood and tumor-infiltrating T cells are known to express VEGF, a potent epithelial mitogen (Blotnick et al., 1994; Freeman et al., 1995). T cells are known to produce and secrete a variety of other growth factors, including HB-EGF and bFGF/FGF-2. Thus, T cells present in the local prostate environment were thought to be capable of secreting potent epithelial and stromal mitogens that promote stromal and glandular hyperplasia.

In the past 5 years, specific inflammatory mediator pathways have been studied in detail to elucidate the potential role of these pathways in BPH pathogenesis. A large number of cytokines and their receptors are seen in BPH tissue (Konig et al., 2004). Specifically, significant levels of IL-2, IL-4, IL-7, IL-17, interferon γ (IFN-γ), and their relevant receptors are found in BPH tissue (Kramer et al., 2002; Steiner et al., 2003a,b). IL-2, IL-7, and IFN-γ stimulate the proliferation of prostatic stromal cells in vitro. Prostatic epithelial cell senescence results in increased expression of IL-8, which can promote proliferation of nonsenescent epithelial and stromal cells (Castro et al., 2004). Macrophage inhibitory cytokine 1 is expressed in normal prostate tissue but significantly downregulated in BPH (Kakehi et al., 2004; Taoka et al., 2004). Chronic inflammation in BPH is also associated with focal upregulation of cyclooxygenase 2 (COX-2) in the glandular epithelium (Wang et al., 2004). To establish potential cause-and-effect relationships between prostatic inflammation and stromal-epithelial hyperplasia, mouse models of autoimmune and bacterial prostatitis have been developed. The POET (prostate ovalbumin expressing transgenic) autoimmune mouse model displays infiltration of lymphocytes, macrophages and neutrophils, which is accompanied by epithelial/stromal thickening and epithelial stem cell expansion (Wang et al., 2015). Bacteria-induced prostate inflammation in mice can also drive epithelial turnover (Kwon et al., 2014b). Correlative evidence in human prostate also demonstrates an expansion of epithelial progenitor cells near sites of inflammation (Liu et al., 2016).

To date, however, no firm cause-and-effect relationships have been established between prostatic inflammation and related cytokine pathways and stromal-epithelial hyperplasia.

Recent work from an Italian laboratory suggests that the metabolic syndrome may be a clinical determinant of a higher risk for prostatic inflammation and thus for male LUTS and BPH, and that androgen receptor activation by testosterone (in a rabbit model) and DHT may have a protective effect on prostatic inflammation (Vignozzi et al., 2012a,b; Gacci et al., 2013). Conditional knockout of the androgen receptor in adult mouse prostate epithelia results in increased secretion of proinflammatory cytokines and immune infiltration (Zhang et al., 2016). In the human, hypogonadism is associated with inflammation (Sorrentino et al., 2011). This work, if confirmed, effectively establishes a link between the role of androgenic steroids and prostatic inflammation in the pathophysiology of male LUTS and BPH.

Kramer et al. (2007) published recent reviews of BPH as a potentially autoimmune disease, and Fig. 144.4 illustrates the immunologic key features of chronic inflammation in BPH and the present interpretation of these changes in the development and progression of BPH. A summary of clinical observations regarding the role of inflammation in clinical BPH suggested it as a therapeutic target (Gandaglia et al., 2013). A more thorough characterization of the immune/inflammatory environment in BPH is needed to identify therapeutic targets.

Genetic and Familial Factors

There is substantial evidence that **BPH has an inheritable genetic component.**

Sanda et al. conducted a retrospective case-control analysis of surgically treated BPH patients and control subjects at Johns Hopkins (Partin and Coffey, 1994; Sanda et al., 1994). The BPH patients were men whose resected prostate weights were in the highest quartile (greater than 37 g) and whose age at prostatectomy were in the lowest quartile. **The hazard-function ratio for surgically-treated BPH among first-degree male relatives of the BPH cases compared with the first-degree male relatives of the controls was 4.2 (95% confidence interval [CI], 1.7 to 10.2), demonstrating a very strong relationship** (Table 144.3). The results did not appear to be caused by differences in health-seeking behavior between the two groups. A segregation analysis showed that the results were most consistent with an **autosomal dominant inheritance pattern.** Utilizing this model, **approximately 50% of men undergoing prostatectomy for BPH before 60 years of age could be attributable to an inheritable form of disease.** In contrast, **only about 9% of men undergoing prostatectomy for BPH after 60 years of age would be predicted to have a familial risk.** In addition, monozygotic twins demonstrate a higher concordance rate of BPH than dizygotic twins (Partin and Coffey, 1994).

BPH, Benign prostatic hyperplasia.

From Sanda MG, Beaty TH, Stutzman RE, et al. Genetic susceptibility of benign prostatic hyperplasia. *J Urol* 152(1):115–119, 1994.

In a community-based cohort study of more than 2000 men, Roberts et al. (1995) found an elevated risk for moderate to severe urologic symptoms in men with a family history of an enlarged prostate and a family history of BPH compared with those with no history. Analysis of the subjects who participated in the US finasteride clinical trial identified 69 men who had three or more family members with BPH, including the proband (Sanda et al., 1997). Regression analysis demonstrated that **familial BPH was characterized by large prostate size, with a mean prostate volume of 82.7 mL in men with hereditary BPH compared with 55.5 mL in men with sporadic BPH.** Serum androgen levels and the response to 5α-reductase inhibition were similar in familial and sporadic BPH. A more recent familial aggregation study in the finasteride database confirmed that a strong family history of early onset and large prostate volume is more likely to be associated with inheritance of risk than symptom severity or other factors (Pearson et al., 2003).

These studies clearly demonstrate the presence of a familial form of BPH and suggest the presence of a gene contributing to the pathogenesis of the disease. The studies of Meikle et al. (1997) also support a genetic basis for BPH. Preliminary studies demonstrate evidence of DNA mutations (White et al., 1990), DNA hypomethylation (Bedford and van Helden, 1987), abnormalities of nuclear matrix protein expression (Partin et al., 1993), miscellaneous genetic polymorphisms (Habuchi et al., 2000a; Konishi et al., 1997; Werely et al., 1996), and abnormal expression of the Wilms' tumor gene (WT-1) (Dong et al., 1997) in human BPH. By analyzing 14 SNPs associated with prostate cancer, genetic variants in 2q31 and 5p15 were found to be associated with aggressive BPH in a Chinese population (Qi et al., 2013). However, the specific gene or genes involved in familial BPH or that contribute to the risk for significant prostatic enlargement in sporadic disease remain to be elucidated.

Other Etiologic Factors

Androgens and soluble growth factors are clearly not the only important factors for the development of BPH. All mammalian prostates studied have testosterone, DHT, and AR as well as most of the known growth factor signaling pathways; however, only dogs and humans develop BPH. Interestingly, another glandular organ that remains androgen responsive throughout life, the seminal vesicle, does not develop hyperplasia. Obviously, other mechanisms or cofactors must be present in these two unique species making them susceptible to the disease. Nonandrogenic substances from the testis, perhaps transmitted through the vas deferens or deferential blood vessels, for example, may play some role (Dalton et al., 1990). Rats with intact testes treated with exogenous androgen demonstrate a greater degree of prostatic growth than castrated rats treated with androgen. Sutkowski et al. (1993) demonstrated that human spermatocele fluid is mitogenic to both human prostatic epithelial and stromal cells in culture. Similar results were seen in castrated versus testes-intact dogs treated with exogenous androgen and exogenous testosterone and estradiol combination (Juniewicz et al., 1994). In addition to increases in prostate weight, the incidence of histologic BPH was significantly higher in the dogs with intact testes. Grayhack et al. (1998) identified a putative substance that may be a candidate for such a factor.

Prolactin has long been speculated to play a role in BPH because of the known effects of this hormone on prostate cells in vitro. Transgenic mice overexpressing the prolactin gene develop significant enlargement of the prostate (Wennbo et al., 1997). However, despite the documented presence of prolactin receptors in the human prostate and low circulating levels of the hormone, the role of prolactin in human prostate disease is unclear.

Molecular profiling, fingerprinting, microarrays, and high-throughput screening tools have uncovered new genes, as well as known genes not previously associated with BPH. Preliminary findings from the Getzenberg laboratory (Minnery and Getzenberg, 2005; Prakash et al., 2002; Sakamoto et al., 2004; Shah et al., 2004) and other groups (Dhanasekaran et al., 2005; Fromont et al., 2004; Henry et al., 2017; Lin-Tsai et al., 2014) suggest that new markers for BPH and new therapeutic targets will be forthcoming in the next few years.

Although there are many mouse models with prostate hyperplasia because of the differences in mouse and human prostate anatomy (Ittmann, 2018) and a poor understanding of the molecular drivers of BPH pathogenesis, there has yet to be developed a mouse model of human BPH. Although a mouse model may never fully recapitulate every aspect of the human disease, greater efforts to model specific aspects of human BPH are needed.

Pathophysiology

The pathophysiology of BPH is complex (Fig. 144.5). **Prostatic hyperplasia increases urethral resistance, resulting in compensatory changes in bladder function.** However, the elevated detrusor pressure required to maintain urinary flow in the presence of increased outflow resistance occurs at the expense of normal bladder storage function. **Obstruction-induced changes in detrusor function, compounded by age-related changes in both bladder and nervous system function, lead to urinary frequency, urgency, and nocturia, the most bothersome BPH-related complaints.** Thus, an understanding of BPH pathophysiology requires detailed insight into obstruction-induced bladder dysfunction.

FIG. 144.5 The pathophysiology of benign prostatic hyperplasia *(BPH)* involves complex interactions among urethral obstruction, detrusor function and dysfunction, and urine production.

Pathology

Anatomic Features

McNeal demonstrated that **BPH first develops in the periurethral *transition zone* of the prostate** (McNeal, 1978) (Fig. 144.6). The transition zone consists of two separate glands immediately external to the preprostatic sphincter. The main ducts of the transition zone arise on the lateral aspects of the urethral wall at the point of urethral angulation near the verumontanum. Proximal to the origin of the transition zone ducts are the glands of the *periurethral zone* that are confined within the preprostatic sphincter and course parallel to the axis of the urethra. All BPH nodules develop either in the transition zone or in the periurethral region (McNeal, 1978, 1990). Although early transition zone nodules appear to occur either within or immediately adjacent to the preprostatic sphincter, as the disease progresses and the number of small nodules increases, they can be found in almost any portion of the transition or periurethral zone. However, **the transition zone also enlarges with age, unrelated to the development of nodules.**

(From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 20[Suppl 3]:S11–S18, 2008.)

One of the unique features of the human prostate is **the presence of the prostatic capsule, which plays an important role in the development of LUTS** (Caine and Schuger, 1987). In the dog, the only other species known to develop naturally occurring BPH, symptoms of bladder outlet obstruction and urinary symptoms rarely develop because the canine prostate lacks a capsule. Presumably the capsule transmits the "pressure" of tissue expansion to the urethra and leads to an increase in urethral resistance. Thus, the clinical symptoms of BPH in humans may be caused by not only age-related increases in prostatic size but also the unique anatomic structure of the human gland. **Clinical evidence of the importance of the capsule can be found in series that clearly document that incision of the prostatic capsule (transurethral incision of the prostate) results in a significant improvement in outflow obstruction, despite the fact that the volume of the prostate remains the same.**

The size of the prostate does not correlate with the degree of obstruction. Thus, other factors such as dynamic urethral resistance, the prostatic capsule, and anatomic pleomorphism are more important in the production of clinical symptoms than the absolute size of the gland. In some cases, predominant growth of periurethral nodules at the bladder neck gives rise to the "middle lobe"

(Fig. 144.7). The middle lobe must be of periurethral origin because there is no transition zone tissue in this area. It is not clear whether middle lobe growth occurs at random in men with BPH or whether there is an underlying genetic susceptibility to this pattern of enlargement.

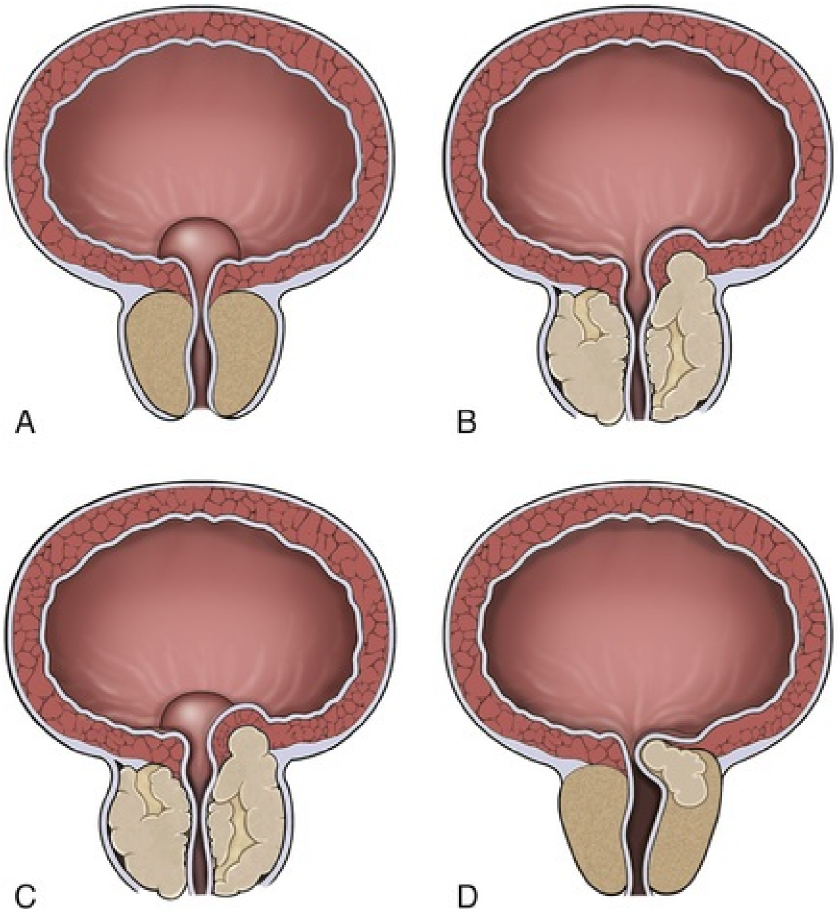

FIG. 144.7 Diagrams of hyperplastic prostatic tissue obstructing the prostatic urethra, forming "lobes." (A) Isolated middle lobe enlargement. (B) Isolated lateral lobe enlargement. (C) Lateral and middle lobe enlargement. (D) Posterior commissural hyperplasia *(median bar).* (After Randall [1931], from Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res*20[Suppl 3]:S11–S18, 2008.)

Histologic Features

BPH is a hyperplastic and not a hypertrophic process (i.e., there is a net increase in the number of cells and not in the size of the cells). Histologic studies document an increase in cell number (McNeal, 1990). In addition, thymidine uptake studies in the dog clearly indicate an increase in DNA synthesis in experimentally induced BPH (Barrack and Berry, 1987). The term *benign prostatic hypertrophy* is pathologically incorrect.

McNeal's studies demonstrate that the majority of **early periurethral nodules are purely stromal in character** (McNeal, 1990). These small stromal nodules resemble embryonic mesenchyme with an abundance of pale ground substance and minimal collagen. It is unclear whether these early stromal nodules contain mainly fibroblast-like cells or whether differentiation toward a smooth muscle cell type is occurring. In contrast, **the earliest transition zone nodules represent proliferation of glandular tissue** that may be associated with an actual reduction in the relative amount of stroma (Fig. 144.8). The minimal stroma seen initially consists primarily of mature smooth muscle, not unlike that of the uninvolved transition zone tissue. These **glandular nodules are apparently derived from newly formed small duct branches** that bud off from existing ducts, leading to a totally new ductal system within the nodule. This type of **new gland formation is quite rare** outside embryonic development. This proliferative process leads to a tight packing of glands within a given area and an increase in the height of the lining epithelium. There appears to be hypertrophy of individual epithelial cells as well. Again, the observed increase in transition zone volume with age appears to be related not only to an increased number of nodules but also to an increase in the overall size of the zone.

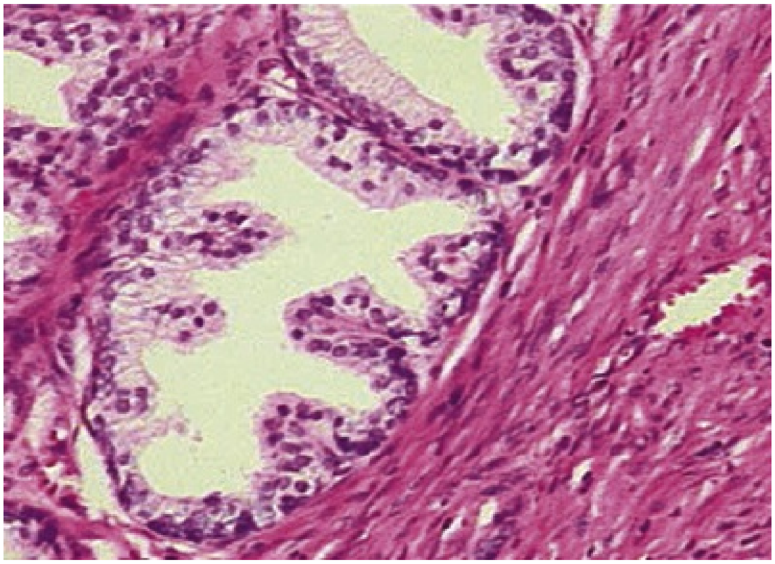

FIG. 144.8 Stromoglandular hyperplasia of the prostate showing glandular *(upper left)* and stromal *(lower right)* tissue (hematoxylin and eosin stain). (From Roehrborn CG. Pathology of benign prostatic

hyperplasia. *Int J Impot Res* 20[Suppl 3]:S11–8, 2008.)

During the first 20 years of BPH development, the disease may be predominantly characterized by an increased number of nodules, and the subsequent growth of each new nodule is generally slow. Then a second phase of evolution occurs in which there is a significant increase in large nodules. In the first phase, the glandular nodules tend to be larger than the stromal nodules. In the second phase, when the size of individual nodules is increasing, the size of glandular nodules clearly predominates (Price et al., 1990).

There is significant pleomorphism in stromal-epithelial ratios in resected tissue specimens, which is largely ignored in molecular studies of BPH. Studies from primarily **small resected glands demonstrate a predominance of fibromuscular stroma** (Shapiro et al., 1992). Larger glands, predominantly those removed by enucleation, demonstrate primarily epithelial nodules (Franks, 1976). However, an increase in stromal-epithelial ratios does not necessarily indicate that this is a “stromal disease”; stromal proliferation may well be caused by “epithelial disease.” A cellular composition and inferred cellular origin for each phenotype has yet to be described (Strand et al., 2017). **This is primarily caused by the lack of proper normal controls in BPH research, where a benchmark of cellular composition and molecular signatures is needed.**

Importance of Prostatic Smooth Muscle

Regardless of the exact proportion of epithelial to stromal cells in the hyperplastic prostate, there is no question that **prostatic smooth muscle represents a significant volume of the gland** (Shapiro et al., 1992) (Fig. 144.9). Although the smooth muscle cells in the prostate have not been extensively characterized, presumably their contractile properties are similar to those seen in other smooth muscle organs. The spatial arrangement of smooth muscle cells in the prostate is not optimal for force generation; however, there is no question that **both passive and active forces in prostatic tissue play a major role in the pathophysiology of BPH.** The factors that determine passive tone in the prostate remain to be elucidated. The series elastic elements in the stromal and epithelial cells and (most important) the ECM contribute to passive tissue force, independent of active smooth muscle contraction. However, **stimulation of the adrenergic nervous system clearly results in a dynamic increase in prostatic urethral resistance. Blockade of this stimulation by α-receptor blockers clearly diminishes this response.** However, α-blockade does not decrease passive tension in the prostate, which may be an equal determinant of urethral resistance.

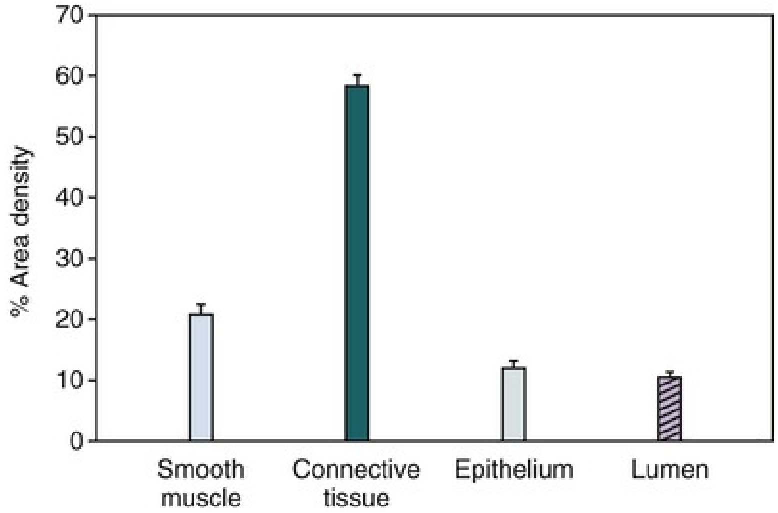

FIG. 144.9 Prostate sections obtained from men with symptomatic benign prostatic hyperplasia were analyzed by double immunoenzymatic staining and quantitative image analysis. The percent area density of smooth muscle and connective tissue is significantly greater than glandular epithelium and glandular lumen area density (mean ± SEM). (From Shapiro E, Becich MJ, Hartanto V, Lepor H. The relative proportion of stromal and epithelial hyperplasia is related to the development of symptomatic benign prostate hyperplasia. *J Urol* 147(5):1293–1297, 1992.)

Several additional observations on the prostatic stromal/smooth muscle cell are important. It is generally assumed that the stromal cells are resistant to the effects of androgen withdrawal. In short-term studies, androgen ablation appears to affect primarily the epithelial cell population. In general, however, stromal cells have much slower turnover rates than epithelial cells. If the effect of androgen ablation is primarily to increase cell death rates, a decrease in stromal cell numbers may not be appreciated until 1 year or more of therapy. Thus, further study is required to determine whether the stromal cell is really resistant to androgen withdrawal. Likewise, it cannot be assumed that hormonal therapy has no effect on the stroma even if stromal cell volumes are not decreased. In a variety of smooth muscle cell systems (e.g., vascular and myometrial), contractile proteins, neuroreceptors, and ECM proteins are regulated by a variety of hormones and growth factors. In vitro, androgens have been shown to modulate the effects of α agonists on prostate smooth muscle cells (Smith et al., 2000). Thus, a given therapy may affect stromal cell function without decreasing the absolute number or volume of cells.

Studies of human tissue samples by Lin et al. (2000) have clearly shown that the smooth muscle cells from men with BPH have a significant downregulation of smooth muscle myosin heavy chain and a significant upregulation of nonmuscle myosin heavy chain. This myosin expression pattern is typical of dedifferentiated smooth muscle and indicates either proliferation or loss of normal modulation pathways.

Active smooth muscle tone in the human prostate is regulated by the adrenergic nervous system (Roehrborn and Schwinn, 2004). The α_1-adrenoreceptor nomenclature has been standardized to reconcile differences in nomenclature based on pharmacologic and molecular studies (Hieble et al., 1995). **Receptor binding studies clearly demonstrate that the α_{1A} is the most abundant adrenoreceptor subtype present in the human prostate** (Lepor et al., 1993a,b; Price et al., 1993)**. Moreover, the α_{1A} adrenoreceptor clearly mediates active tension in human prostatic smooth muscle.** It is still unclear whether other factors may regulate smooth muscle contraction. Endothelin and endothelin receptors have been reported in human prostate (Imajo et al., 1997; Kobayashi et al., 1994a,b; Walden et al., 1998). However, the physiologic role of this potent contractile agent in prostate smooth muscle function remains to be defined. Various components of the kallikrein-kinin system (e.g., bradykinin) may play a role in the regulation of both smooth muscle proliferation and contraction in the prostate (Srinivasan et al., 2004; Walden et al., 1999).

The presence of type 4 and type 5 phosphodiesterase isoenzymes in the prostate and the detrusor muscle of the bladder implies that phosphodiesterase inhibitors may be appropriate candidate therapies for BPH-related LUTS (Uckert et al., 2001, 2008, 2009). In fact, placebo-controlled trials have verified a beneficial effect of commercially available drugs for the treatment of erectile dysfunction (ED) in men with LUTS and BPH (McVary et al., 2007; Roehrborn et al., 2008; Stief et al., 2008).

The role of adrenergic stimulation in the prostate may exceed simple smooth muscle contraction. Adrenergic neurotransmitters are known to regulate expression of contractile protein genes in cardiac myocytes (Kariya et al., 1993) and to be involved in the development of cardiac hypertrophy (Matsui et al., 1994). Interestingly, evidence suggests that testosterone may regulate the expression of adrenergic receptors, at least in the kidney (Gong et al., 1995). It is possible that adrenergic neurotransmitters may play a role in prostatic smooth muscle cell *regulation* and contraction (Smith et al., 2000). α-Adrenergic blockade in patients with documented BPH leads to a significant downregulation of normal contractile protein gene expression, specifically smooth muscle myosin heavy chain.

Autonomic nervous system overactivity may contribute to LUTS in men with BPH. McVary et al. (2005) demonstrated that autonomic nervous system activity, as measured by a standard set of physiologic tests, plasma, and urinary catecholamines, correlates positively with symptom score and other BPH measures. Serum norepinephrine increase after tilt predicted prostate size (transition zone).

The Bladder's Response to Obstruction

Current evidence suggests that the bladder's response to obstruction is largely an adaptive one. However, it is also clear that many lower tract symptoms in men with BPH or prostate enlargement are related to obstruction-induced changes in bladder function rather than to outflow obstruction directly. Approximately one-third of men continue to have significant voiding dysfunction and mostly storage symptoms after surgical relief of obstruction (Abrams et al., 1979). Obstruction-induced changes in the bladder are of two basic types. First, the **changes that lead to *detrusor instability* or decreased *compliance* are clinically associated with symptoms of frequency and urgency.** Second, the **changes associated with decreased *detrusor contractility* are associated with further deterioration in the force of the urinary stream, hesitancy, intermittency, increased residual urine,** and (in a minority of cases) detrusor failure. Acute urinary retention (AUR) should not be viewed as an inevitable result of this process. Many patients presenting with AUR have more than adequate detrusor function, with evidence of a precipitating event leading to the obstruction.

Much of our knowledge of the detrusor's response to obstruction is based on experimental animal studies. Limited information is available on the natural history of the human bladder's response to obstruction. Gosling et al. demonstrated that **the major endoscopic detrusor change, trabeculation, is caused by an increase in detrusor collagen** (Gosling and Dixon, 1980; Gosling et al., 1986). Severe trabeculation is associated with significant residual urine (Barry et al., 1993), suggesting that incomplete emptying may be caused by increased collagen rather than impaired muscle function. Severe trabeculation, however, is seen in fairly advanced disease. In experimental animal models, **the initial response of the detrusor to obstruction is the development of smooth**

muscle hypertrophy (Levin et al., 1995, 2000). It is likely that this **increase in muscle mass, although an adaptive response to increased intravesical pressure and maintained flow, is associated with significant intracellular and extracellular changes in the smooth muscle cell that lead to detrusor instability and in some cases impaired contractility.** Obstruction also induces changes in smooth muscle cell contractile protein expression, impaired energy production (mitochondrial dysfunction), calcium signaling abnormalities, and impaired cell-to-cell communication (Levin et al., 1995, 2000). The study of bladder trabeculation in the epidemiology of BPH and bladder outlet obstruction suffers from a universal definition and a widely accepted grading system of trabeculation. A recent attempt to create such a grading system demonstrated acceptable correlation with urodynamic parameters (Cho et al., 2013).

There is considerable evidence that the response of the detrusor smooth muscle cell to stress (increased load related to outlet obstruction) is not as adaptive as the response of skeletal muscle to stress. In the latter case, a relatively normal repertoire of contractile protein genes are upregulated, and an increased number of normally organized contractile units assemble in the muscle cell. In the detrusor smooth muscle cell, load-induced hypertrophy leads to a change in myosin heavy chain isoform expression (Cher et al., 1996; Lin and McConnell, 1994) and to a significant alteration in the expression of a variety of thin filament–associated proteins (Mannikarottu et al., 2005a,b, 2006). Taken together, these observations strongly suggest that smooth muscle cells revert to a secretory phenotype in response to obstruction-induced hypertrophy. One consequence of this phenotypic switch is increased ECM production. The detrusor smooth muscle cell is a key contributor to the complex of symptoms associated with prostatic obstruction. Additional research in this area is required (Christ and Liebert, 2005).

In experimental animal models, unrelieved obstruction is associated with the development of significant increases in detrusor ECM (collagen) (Levin et al., 1995, 2000). This also appears to be the case in the human, although cause-and-effect relationships have not been established (Gosling et al., 1986). In addition to obstruction-induced changes in the smooth muscle cell and ECM of the bladder, there is increasing evidence **that obstruction may modulate neural-detrusor responses** as well (Clemow et al., 1998, 2000; Steers et al., 1990, 1999). Altered neural control of micturition has been noted in aging rats, including reduced bladder contractility, impaired central processing, and altered sensation (Chai et al., 2000).

Fusco et al proposed after conducting an exhaustive review of the literature a three-stage model of bladder wall remodeling involving an initial hypertrophy phase, a subsequent compensation phase, and a later decompensation involving urothelium, suburothelium, detrusor smooth muscle cells, detrusor extracellular matrix, and bladder nerves. Cyclic stretch, increased hydrostatic and cyclic hydrodynamic pressure, and hypoxia are stimuli capable of modulating multiple signaling pathways involved in this remodeling process (Fusco et al., 2018).

A late response of the bladder to longstanding obstruction may be detrusor underactivity or underactive bladder, representing an end-stage condition with limited therapeutic options and found with increasing prevalence in elderly men and women (Osman and Chapple, 2018; Osman et al., 2018).

Independent of obstruction, aging produces some of the same changes in bladder function, histology, and cellular function (Nordling, 2002). There is suggestive evidence from animal models that atherosclerosis and the resultant chronic bladder ischemia or hypoxia induced by other mechanisms (e.g., increased bladder wall tension) may contribute to bladder pathology (Azadzoi, 2003; Azadzoi et al., 1999, 2003, 2008; Tarcan et al., 1998).

Key Points

- Androgens are necessary for maintenance but not growth of the prostate and are anti-inflammatory.
- Inflammation is correlated with prostatic enlargement, but its causal role is unclear.
- Intrapatient and interpatient anatomic pleomorphism confounds a cell type–specific molecular understanding of BPH and possibly contributes to therapeutic resistance.
- Animal models do not fully recapitulate human BPH because of anatomic differences, and there is a poor mechanistic understanding of the human disease.
- A heritable form of BPH exists, but precise mutations are unidentified.
- A mechanistic understanding of the secondary effects of prostatic obstruction on bladder contractile and neuromodulatory functions could improve clinical outcomes in patients with BPH/LUTS.

Epidemiology and Natural History

Definitions

The study of epidemiology determines the distribution and determinants of diseases in man. From this evolve the components of descriptive epidemiology, which is the description of disease incidence, mortality, and prevalence by person, place and time, and analytical epidemiology, which is the search for determinants of disease risk that may serve to increase prospects for prevention. Epidemiologists assess and compare rates of diseases within one population stratified by sex, age, and other demographic and socioeconomic parameters, and among populations of different culture, ethnicity, lifestyle, and diet.

The following definitions of rates are important to understand:

- Incidence: number of diseased people per 100,000 population per year
- Prevalence: number of existing cases per 100,000 population at a distinct target date
- Mortality: number of deaths per 100,000 population per year
- Fatality: number of deaths per number of diseased

Although the incidence rate (rate of people developing the condition in 1 year) is of preeminent interest for highly fatal conditions (those with a high fatality and mortality rate), the prevalence rate (number of men having the condition at a given point in time) is of greater interest for conditions such as BPH, which are rather benign in their course.

There is no globally accepted epidemiologic definition of BPH, and thus, prevalence and incidence rates must be viewed in the context of the definitions chosen by the investigator reporting the data (Barry, 1990). The prevalence of BPH thus can be calculated based on histologic criteria (autopsy prevalence) or clinical criteria (clinical prevalence). Because clinical definitions vary widely, it is easier to compare the autopsy or histologic prevalence of BPH. Despite the low mortality and fatality rates for BPH in modern series, a review of these data is interesting and revealing from a historical point of view.

Lastly, descriptive epidemiologic studies can be divided into *cross-sectional* (population stratified by baseline parameters is assessed one single time to determine if and how certain measures change depending on the parameter of interest) and *longitudinal* (population is assessed at baseline and at regular intervals to study the changes in parameters of interest stratified by age or other demographic criteria). It is obviously easier to perform cross-sectional studies because of the cost and logistical difficulties involved with longitudinal follow-up of a cohort over time. The majority of studies addressing LUTS and clinical BPH are cross-sectional in nature and are discussed later. Further, there are by definition no longitudinal autopsy studies of any condition, and histologically based longitudinal studies are exceedingly difficult to carry out because of the need for repetitive tissue procurement.

Descriptive Epidemiologic Studies

Histologic or Autopsy Prevalence

The definition of BPH is the presence of stromo-glandular hyperplasia on a surgical specimen or in the case of autopsy series in whole prostates removed after death from men not dying from prostate conditions. The 1984 landmark study by Berry et al. summarized the data from five studies demonstrating that no men younger than 30 years of age had evidence of BPH and that the prevalence rose with each age group, peaking at 88% in men in their 80s. Fig. 144.10 demonstrates the age-stratified prevalence based on several rigorously performed autopsy studies in the United States, the United Kingdom, Austria, Norway, Denmark, China, Japan, and India. The prevalence increases rapidly in the fourth decade of life, reaching nearly 100% in the ninth decade. It is striking that the age-specific autopsy prevalence is remarkably similar in all populations studied regardless of ethnic and geographic origin (Berry et al., 1984; Carter and Coffey, 1990; Franks, 1953; Harbitz and Haugen, 1972; Haugen and Harbitz, 1972; Karube, 1961; Holund, 1980; Moore, 1943; Pradhan and Chandra, 1975; Swyer, 1944).

Cross-Sectional Studies of Clinical Prevalence

Descriptive epidemiology relies on the presence of a single universally accepted definition of “disease.” The definitions of BPH, however, have undergone several changes in the past decade, and at present, no single criterion can be applied. In the past, the term *prostatism* was used, incorrectly referring to the prostate as the sole source of the typical LUTS found in aging men. Paul Abrams coined the term *LUTS* to replace the old and inappropriate term *prostatism*

(Chapple et al., 2008). When evaluating elderly men, one can therefore stratify them by the level of LUTS into mildly, moderately, and severely symptomatic according to a standardized symptom severity and frequency questionnaire (Barry et al., 1992a). It is important to recognize that BPH is only one potential cause for LUTS, which also may be caused by bladder, urethral, neurogenic, and as of now unknown causes. Patients can also be classified based on the degree of prostatic enlargement as measured by digital rectal examination (DRE), transrectal ultrasonography (TRUS), or magnetic resonance imaging (MRI), and lastly by the presence and degree of bladder outlet obstruction as measured by flow rate recordings or invasive pressure-flow studies**.** The diagram in Fig. 144.1 illustrates the difficulties in using different disease definitions. Of all men older than 40 years of age, a certain proportion will develop histologic hyperplasia of the prostate (i.e., BPH). Of these, some but not all will develop LUTS, and others may have LUTS caused by reasons other than BPH (e.g., overactive bladder or other bladder- and detrusor-related conditions, urethral stricture, stones, inflammation). Prostate enlargement occurs in some but again not all men with histologic BPH and LUTS, and some men with enlarged glands may not have any symptoms. Lastly, urodynamically proven obstruction may be present in men who have either one, several, or all of histologic BPH, LUTS, enlarged glands, and others yet may have obstruction without having evidence of BPH (e.g., urethral stricture, prostate cancer, primary bladder neck sclerosis). In addition to the mere enumeration of symptoms by frequency of occurrence, the bother associated with the symptoms, interference with activities of daily living, and the impact the symptoms have on quality of life are important distinguishing characteristics.

Accordingly, when studying the prevalence of “clinical BPH” (admittedly an imprecise term describing the constellation of LUTS, bother, interference, quality-of-life impact, with or without enlargement, obstruction), disease definitions may be applied that take either one or several of these items into consideration. For the subsequent discussion, it is important to recognize that very few if any clear cutoff points have been established that allow differentiation among disease states. For example, one might argue that a prostate volume more than 30 mL constitutes “clinical BPH,” but others might argue for a higher or lower cutoff point. Similar observations apply to symptom severity above or below a certain threshold, degrees of obstruction, and so on. Thus, rather than describing truly the prevalence of “a disease” in populations, one can describe the distribution of certain attributes of such disease in different populations stratified by age. Fig. 144.11 illustrates the different estimates of prevalence of “disease” when different definitions are applied ranging from autopsy prevalence to a combination of clinical threshold parameters and insurance examination data (Berry et al., 1984; Bosch et al., 1995; Chute et al., 1993; Garraway et al., 1991; Gu et al., 1994; Guess, 1995; Jolleys et al., 1994; Moon et al., 1995; Overland et al., 2001).

Symptom Severity and Frequency

From a pragmatic point of view, studies of symptom severity and frequency are of greatest importance in a disease, which is rarely fatal and is characterized by its effect on quality of life. The development, validation, and translation with cultural and linguistic validation of the standardized, self-administered seven-item AUA Symptom Index (AUASI; also known as the International Prostate Symptom Score [IPSS]) has been a pivotal event in the clinical research of LUTS and BPH (Barry et al., 1992a, 1992b; O'Leary et al., 1992). With the total score running from 0 to 35 points, patients scoring 0 to 7 points are classified as mildly symptomatic, those scoring from 8 to 19 points as moderately symptomatic, and those scoring 20 to 35 points as severely symptomatic. The instrument is an integral part of virtually every epidemiologic study and treatment studies in the field, and the availability of validated translations in many common languages allows cross-cultural comparisons of unprecedented scope. Socioeconomic factors do not seem to influence responses to the questionnaire (Moon et al., 1994), and fundamentally similar responses are obtained when the questionnaire is self-administered, read to the patient, mailed in or administered in some other way (Barry et al., 1995a), or readministered in a scrambled format (Barnboym et al., 1999). However, there is no question that subtle differences in comprehension of the translated questionnaire, and different perception of the symptoms, willingness to admit to the symptoms, acceptance of symptoms as a natural sign of aging, and other factors are at least partially the cause for cross-cultural differences in symptom severity reported in the literature. Fig. 144.12 shows the prevalence of at least moderate to severe symptoms stratified by decade of life as reported in 11 cross-sectional population-based studies from around the world (Bosch et al., 1995; Chute et al., 1993; Garraway et al., 1991; Hunter et al., 1994, 1996; Moon et al., 1995; Norman et al., 1994; Overland et al., 2001; Sagnier et al., 1996;Tsukamoto et al., 1995). A very large international investigation of LUTS in Asian men was undertaken by Homma et al. (1997) in which 7588 men from Japan, China, Taiwan, Korea, the Philippines, Thailand, Singapore, Pakistan, India, and Australia were queried. The finding of 18%, 29%, 40%, and 56% of men in their 40s, 50s, 60s, and 70s having moderate to severe symptoms is in line with the other studies reported both from Asia and from Europe and North America. In addition to the major community-based studies listed, other studies have been published with similar findings, but often done under less stringent conditions (Nacey et al., 1995; Tay et al., 1996). Despite the significantly different proportion of men admitting to moderate to severe symptoms, a clear trend toward an increase in symptom severity and frequency with advancing age is noticeable in all reported studies.

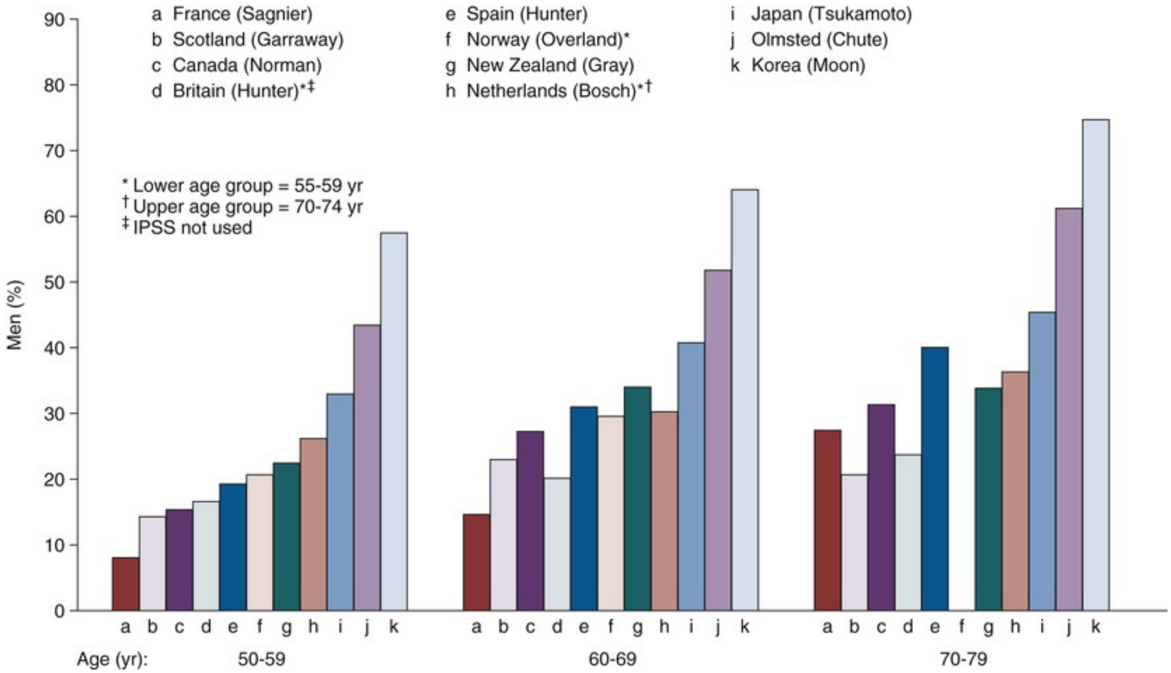

FIG. 144.12 Prevalence of at least moderate to severe symptoms stratified by decade of life as reported in cross-sectional population-based studies from around the world. Bother, Interference, and Health-Related Quality of Life

Bother and interference with activities of daily living caused by LUTS are equally if not more important than the enumeration of symptom frequency and severity alone (Garraway et al., 1993; Roberts et al., 1994b). Embarrassment resulting from symptoms has been found to be an important determinant in seeking medical care (Roberts et al., 1994b). LUTS and clinical BPH affect overall quality of life as measured with the Medical Outcomes Trust Short-Form (SF-36) only marginally (Hunter et al., 1995). Accordingly, several instruments were developed and validated to assess bother, interference, and the disease-specific quality of life and sexual function (Barry et al., 1995b; Donovan et al., 1996; Epstein et al., 1992; Hansen et al., 1995; Lukacs et al., 1995; O'Leary et al., 1995).

These instruments have not been as widely applied to cross-sectional descriptive epidemiologic studies as compared with the IPSS. However, as observed for symptom severity and frequency, both bother and interference scores increase with advancing age, and disease-specific health-related quality of life (HRQoL) measures are significantly poorer in men with higher symptom frequency and severity ratings in population-based studies done in Olmsted County, US; Forth Valley, Scotland; France; and a small fishing village in Japan (Shimamaki-Mura) (Girman et al., 1998).

A recent multi-institutional study funded by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) under the umbrella name LURN

(Symptoms of Lower Urinary Tract Dysfunction Research Network) has published their initial findings. Among other findings, a high incidence of urinary incontinence in men presenting with LUTS was observed, casting doubt on the IPSS as the single best tool to assess LUTS in men as it has no question specific to stress or urge incontinence (Griffith et al., 2018; Helfand et al., 2018; Yang et al., 2016).

Prostate Size

Prostate size can be estimated by DRE, although the reliability across observers is in general considered poor (Roehrborn et al., 1997). A recent analysis of the PLCO trial verified the significant errors associated with the DRE-assessed prostate size (Pinsky et al., 2006). In addition, DRE tends to underestimate true prostate size as determined by TRUS or other imaging modalities. The magnitude of the underestimation increases with increasing prostate size from 25% up to 50% or more (Roehrborn et al., 1997). For the purpose of epidemiologic studies, TRUS and MRI measurements are preferred, although MRI measurements are somewhat expensive when attempting cross-sectional examinations of populations. TRUS volume measurements using the prolate ellipsoid volume formula are the most widely accepted measure of prostate volume with reasonable statistical performance characteristics, particularly when performed by a single or several well-trained examiners (Sech et al., 2001). Three-dimensional TRUS appears to provide even more accurate measurements, although such technology is not available in urologists' offices for the most part (Giubilei et al., 2005).

In general, in all cross-sectional studies prostate volume as assessed by TRUS has been found to increase slowly but steadily with advancing age. The slight differences in the absolute volume measures, and the different slopes of increase with advancing age may be caused by differences in the population examined as follows (Fig. 144.13).

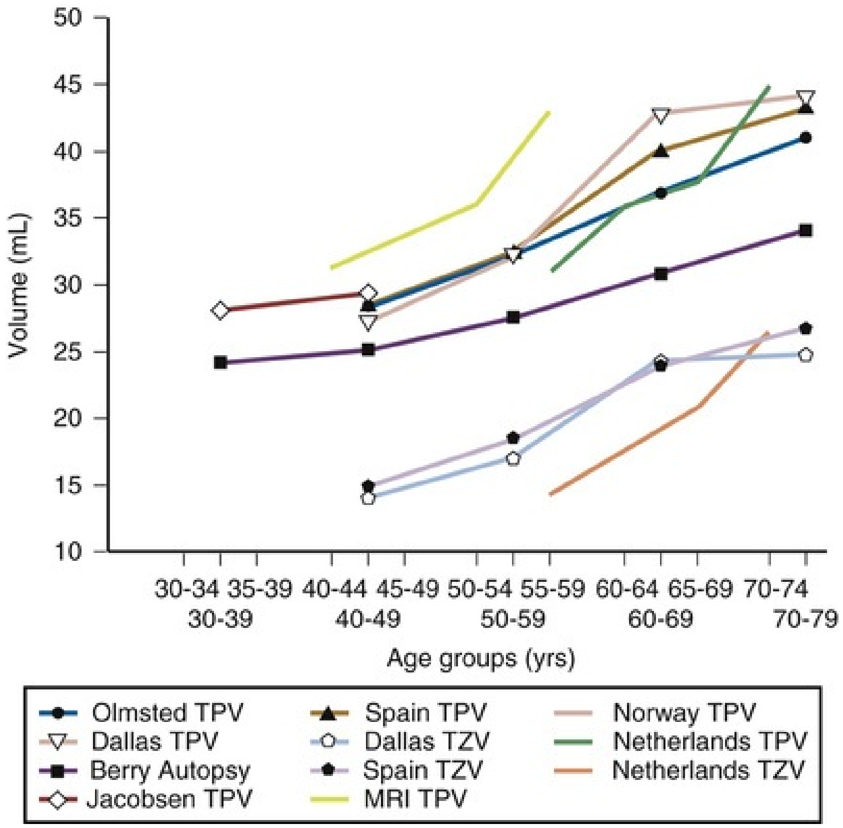

FIG. 144.13 Mean estimates for total prostatic volume *(TPV)* and transitional zone volume *(TZV)* based on one autopsy series (Berry et al, 1984), one series of baseline MRI measurements in men with alopecia (Roehrborn et al, 2000b), and cross-sectional population-based studies (Torp-Pedersen et al, 1988; Oesterling et al, 1993; Bosch et al, 1994; Benaim et al, 1998; Chicharro-Molero et al, 1998; Overland et al, 2001).

A cohort of 344 men between 40 and 60 years of age with no evidence of BPH enrolled in an alopecia study had baseline endorectal coil MRI measurements done (Roehrborn et al., 2000c). Mean TPV increased from 31.3, 33.7, 36.1 to 43.1 mL in increments of 5 years. MRI tends to yield prostate volume measurements approximately 10% larger compared with TRUS. A series of 100 men 40 to 80 years of age without BPH or LUTS underwent TRUS measurements of TPV and TZV. TPV increased from 22.1, 29.1, 41.5 to 43.2 mL by decade, and TZV from 7.2, 9.9, 19.0 to 19.6 mL (Benaim et al., 1998). A cross-sectional study of 611 Norwegian men from 55 to 70 years of age exhibited increases in TPV from 26.5, 31.0 to 32.0 mL in increments of 5 years (Overland et al., 2001), and Jakobsen examined patients between 30 and 50 years of age by TRUS, the mean TPV being 23.9 and 25.7 mL per decade of life (Jakobsen et al., 1988). TPV and TZV were assessed in 1104 men older than 40 years of age in a Spanish cross-sectional study, yielding increases from 23.4 to

41.9 mL for TPV and from 7.9 to 21.9 mL for TZV (Chicharro-Molero et al., 1998). Finally, the baseline data from the Olmsted County Study of Urinary Symptoms in Men provided data on men from 40 to 79 years of age (Oesterling et al., 1993).

Overall, TPV increases in these cross-sectional studies from approximately 25 mL for men in their 30s to 35 to 45 mL for men in their 70s, and TZV increases from 15 mL to 25 mL for similarly aged men. The similarities between the TPV and TZV measurements done in the different studies are striking, particularly when considering the different measurement methods used (see Fig. 144.13).

Measures of Obstruction

Subvesical obstruction can only be measured by invasive pressure-flow studies, and nonintubated free flow rates provide at best an indirect measure for the probability of obstruction being present (Abrams, 1995). Unfortunately, no large-scale cross-sectional studies have been done employing pressure-flow studies because of the invasive and costly nature of the test, and it is unlikely that significant datasets will ever become available.

It is commonly accepted that a maximum flow rate of less than 10 mL/sec indicates a high probability of obstruction, and a flow rate of greater than 15 mL/sec indicates a low probability, with the 10- to 15-mL/sec range presenting an intermediate range. The utility of this categorization is reduced by several observations. First, the maximum flow rate is somewhat dependent of the voided volume (Girman et al., 1993). This has prompted some to propose a nomogram to correct for this phenomenon; however, at present no single nomogram is accepted universally (Beck and Gaudin, 1969; Drach and Steinbronn, 1986; Haylen et al., 1989; Scott and McIlhaney, 1961; Siroky et al., 1979, 1980; Susset et al., 1973; von Garrelts, 1956, 1957, 1958). A high degree of diurnal variability (Golomb et al., 1992) and within subject day-to-day variability (Barry et al., 1995c) further reduces the utility of flow rate recording in defining disease.

Aging men and women experience a decrease in the maximum urinary flow rate, which is nearly linear in nature. In the Olmsted County Study, the median flow rate decreased from 20.3 mL/sec for men 40 to 44 years of age to 11.3 mL/sec for men 75 to 79 years of age (Girman et al., 1993), and similar declines have been reported from other cross-sectional studies. When applying combined thresholds such as at least moderate symptoms of greater than 7 points on the IPSS **and** a maximum flow rate of less than 15 mL/sec, in the Olmsted County study, 17% of men in their 50s, 27% of men in their 60s, and 35% of men in their 70s would fall into such category (Jacobsen et al., 1995), versus 14.4%, 28.6%, and 38.7% of men in the respective age groups in the Spanish population-based study (Chicharro-Molero et al., 1998).

Analytical Epidemiologic Studies

Analytical epidemiologic studies address the search for determinant of a disease. Inasmuch as a clear disease definition is lacking, such search could attempt to find determinants for LUTS, prostate growth, and/or bladder outlet obstruction, consistent with the previously outlined concepts. The presence of functioning testes at time of puberty (hormonal factor) as a required permissive element has long been established and accepted (McConnell, 1991), and age has been shown to be the most critical determinant of all aspects of this complex entity. Numerous other demographic and environmental factors have been suggested as risk factors or contributors to the disease process.

Religion

The case-control study by Morrison (1978), the cohort study by Lytton et al. (1968), and the Normative Aging Study by Glynn et al. (1985) all revealed Jewish religion to be associated with a higher prostatectomy rate (2.2 to 2.6 fold increase). The fact, however, that Jewish religion is not associated with an increase in the *diagnosis* of BPH, allows the speculation that Jewish patients are more likely to see a physician or to be offered surgical therapy.

Socioeconomic Factors

Araki et al. (1983) found higher rates of BPH in higher-income groups. In contrast, Glynn et al. (1985) reported higher rates of surgery in lower-income groups. One might argue that higher-income groups might have better access to health care, and lower-income groups might submit more readily to the suggestion of a surgical procedure. Education and socioeconomic status do not influence responses to the IPSS (Badia et al., 2001; Moon et al., 1994), but they do appear to influence both expectations from treatment for BPH and perception of improvement, with patients in higher-income strata requiring a larger drop in symptom scores after treatment to perceive subjectively similar levels of improvement (Padley et al., 1997). This finding suggests at least some impact of socioeconomic factors if not in the growth of the prostate or measures of obstruction, but likely in the perception of symptoms. Data from the Olmsted

County study suggest a relationship between care-seeking behavior and physician visit and retirement status. Bivariate analysis suggested significant associations between a propensity to seek care for physical reasons and retirement (OR 2.0; 95% CI, 1.1 to 2.6), age of 65 years or more (OR 1.9; 95% CI, 1.5 to 2.4), incomplete high school education (OR, 1.6; 95% CI, 1.1 to 2.2), and annual income of less than $25,000 (OR, 1.4; 95% CI, 1.1 to 1.9). Multivariable logistic regression analysis demonstrated that retired men were more likely to have a high propensity to seek care (OR, 1.7; 95% CI, 1.2 to 2.4), with the other variables no longer being significant (Roberts et al., 1997a).

Recently our understanding of the impact of some socioeconomic factors on LUTS and BPH had deepened with the help of two studies, the EPIC and EpiLUTS, and the Boston Area Community Health (BACH) studies (Kaplan et al., 2009; Rosen et al., 2008) (Table 144.4). It is likely that the longitudinally designed BACH study with a balanced enrollment of men and women stratified by age and race/ethnicity will contribute in the future significantly to our understanding of LUTS in both men and women. A symptom-based cluster analysis was performed in both cohorts and, remarkably, similar clusters of symptoms were identified, allowing for an in-depth analysis of their association with comorbidities and other factors (Rosen et al., 2008). In the BACH study, decreasing household income and increasing difficulties in paying for health care were associated with increasingly more severe symptom clusters (Hall et al., 2009).

TABLE 144.4

Overview of the EpiLUTS and BACH Studies

EPILUTS	BACH
DESCRIPTION	
Cross-sectional, population-representative, Internet-based survey conducted in the United States, the United Kingdom, and Sweden in 30,000 (US, 20,000; UK, 7500; Sweden, 2500) men and women aged 40–99 years (mean age, 56.6 years)	Population-based epidemiologic survey among 5503 randomly selected adults residing in Boston aged 30–79 years in three race/ethnic groups (2301 men, 3202 women; 1767 black, 1877 Hispanic, 1859 white respondents)
LUTS PREVALENCE	

1 LUTS at least sometimes: 72.3% (men), 76.3% (women) 1 LUTS at least often: 79.99% (men), 52.5% (women)	LUTS (AUASI ≥8): 18.7% (men), 18.6% (women); increased with age (10.5% for 30–39 years to 25.5% for 70–79 years), no difference by race/ethnicity (16.2%–19.3%)
BOTHER	
Rates of bother were lower for LUTS classified as at least “sometimes” than those classified as at least “often” However, leaking urine during sexual activity, which was reported infrequently, was highly bothersome (82.1% men; 87.2% women), whereas terminal dribble, which was reported frequently, was less bothersome (40.6% men; 40.2% women)	Mean bother scores were higher in those with LUTS (vs. no LUTS) and for women vs. men
TREATMENT SEEKING	
Treatment seeking was low but most common in those in the voiding + storage + postmicturition subgroup: 29.1% men, 27.5% women; prescription medication use was also highest in this subgroup (17.6% and 10.4%, respectively)	Prescription medication use for urinary symptoms was low even among those with AUASI ≥8, at 9.8% (men) and 2.1% (women)
COMORBIDITIES	
Comorbid conditions were most common in the voiding + storage + postmicturition subgroup with significant associations for LUTS with arthritis, asthma, chronic anxiety, depression, diabetes (men only), heart disease, irritable bowel syndrome, neurologic conditions, recurrent UTI, and sleep disorders; childhood nocturnal enuresis was significantly associated with most LUTS subgroups	LUTS (AUASI ≥8) was associated with heart disease, diabetes (men only), and depression

Egan et al. found no evidence in the NHANES study that rural/urban status was not associated with significantly increased adjusted odds of either recognized or unrecognized LUTS/BPH (Egan et al., 2015).

Sexual Activity and Vasectomy

Ekman suggested that the increase in the fibromuscular stroma is a result of sexual activity (Ekman, 1989), and many authors since then have attempted to find relevant associations. Morrison reported a 49% reduction in risk for prostatectomy in widowed versus single men (Morrison, 1992). Similar association could not be verified by other authors. Cross-sectional data from the Olmsted County study suggest that the frequency of ejaculation has no effect on LUTS, peak urinary flow rates, or prostate volume; the apparent protective association appears to be an artifact caused by the confounding effects of age (Jacobsen et al., 2003). The decrease in sexual ability and frequency of sexual activity with advancing age, exactly when the prevalence of BPH increases, in fact might suggest a reverse relationship, namely a causative effect of BPH on sexual function (Altwein and Keuler, 1992).

Recent evidence suggests a strong correlation between the severity of LUTS and impairment of sexual function, that is, ED and ejaculatory disturbances (Boyle et al., 2003; Chung et al., 2003; Rosen et al., 2003). Cross-sectional questionnaire-based data from various countries suggest that ED and ejaculatory disturbances increase with advancing age, but also within each decade of life with increasing LUTS symptom severity (Fig. 144.14). Although these correlations do not necessarily imply a causative mechanism, it is possible that similar pathophysiologic events underlie the development of both problems in the aging male, the most obvious being ischemia in both the genital and lower urinary tract organs (McVary, 2005). A logistic regression analysis of the EpiLUTS data documented as well a strong relationship between various domains of sexual and ejaculatory dysfunction and LUTS (Wein et al., 2009) (Table 144.5).

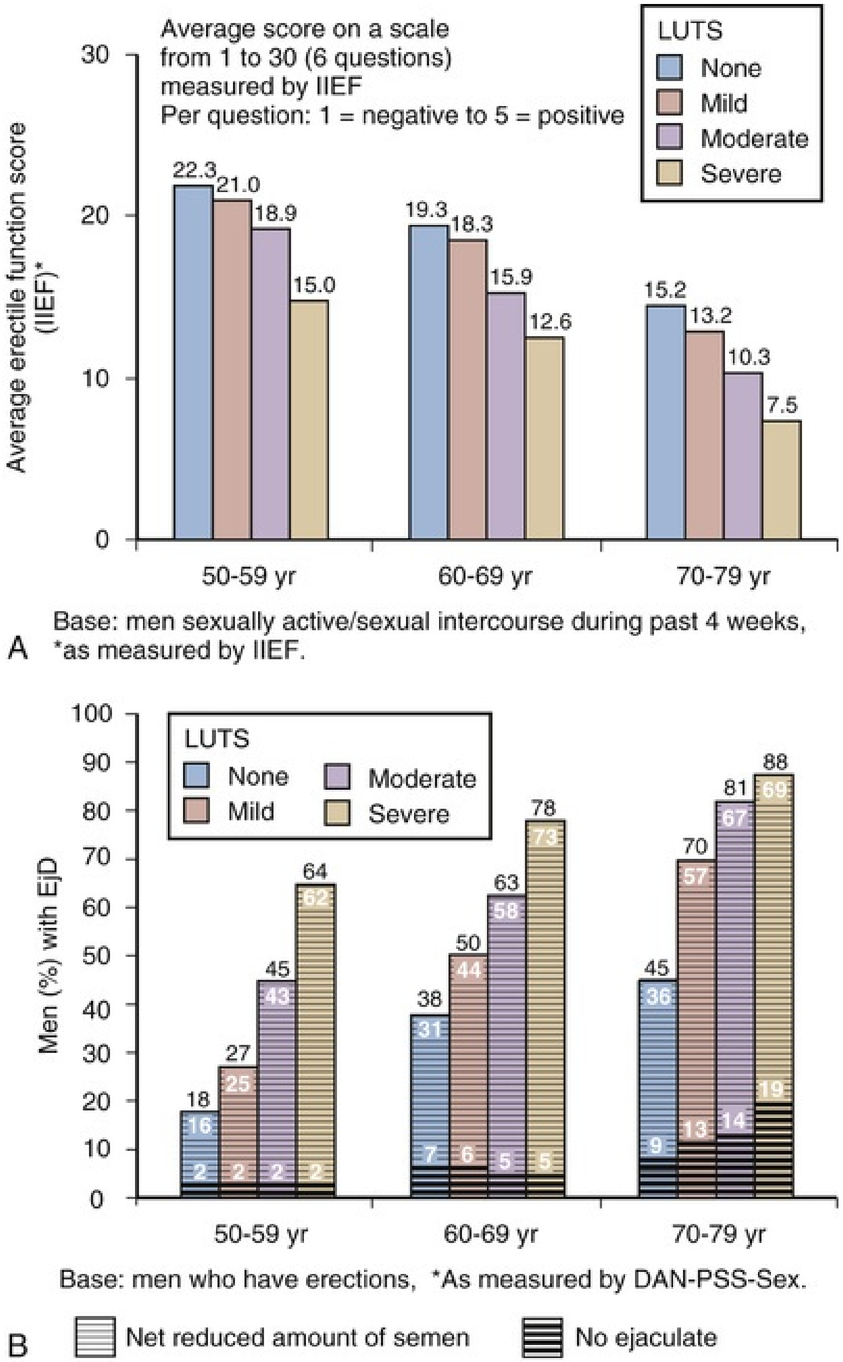

FIG. 144.14 Erectile function (A) decreases and ejaculatory disturbances (B) increase with advancing age, but within each decade of life they also decrease and increase, respectively, with increasing severity in lower urinary tract symptoms (LUTS). *DAN-PSS,* Danish Prostatic Symptom Score; *IIEF,* International Index of Erectile Function. Sidney analyzed the Kaiser Permanente Database and initially found a RR (Risk Ratio) of 1.2 for the diagnosis of BPH among men who had a vasectomy (Sidney, 1987). However, after 5 years of follow-up, the RR was 0.97 and not significant. There does not appear to be a relationship between vasectomy and BPH development or prostate size (Jakobsen et al., 1988), and in the Massachusetts Male Aging Study, Meigs et al. (2001) did not find that vasectomy increased the risk for being diagnosed with BPH.

Alcohol and Liver Cirrhosis

Alcohol may effect the level of plasma testosterone by affecting the production as well as the clearance of testosterone (Chopra et al., 1973). Despite this hypothetical reason for a lower incidence of BPH, inverse relationships have been described. Both Morrison (1992) and Sidney (1991a) reported by multivariate analysis an adjusted RR of 0.49 and age-adjusted RR of 0.75, respectively, for the risk of having surgery for BPH when taking in more than three glasses of alcohol per day. However, one might argue that the poorer health in heavy drinkers might bias physician against surgery. Glynn et al. (1985) in fact found no increased risk for either the clinical diagnosis or surgical rates. A recent analysis of the prostate cancer prevention trial (PCPT) showed as well an inverse relationship between a diagnosis of BPH and alcohol intake, that is, a somewhat protective effect (Kristal et al., 2008). A meta-analysis of alcohol intake, BPH, and LUTS demonstrated that consumption of alcohol decreases the likelihood of BPH in all six strata, but not LUTS. Compared with no alcohol, an alcohol intake of greater than or equal to 36 g/day was associated with a 35% decreased likelihood of BPH (OR 0.65) (Rees, 2009).

Of five studies examining the relationship between liver cirrhosis and BPH based on autopsy material, four found a lower prevalence of BPH in men with cirrhosis (Bennett et al., 1950; Frea et al., 1987; Robson, 1966; Stumpf and Wilens, 1953), and one study (admittedly with some design flaws) found a higher prevalence (Wu, 1942). Because most cirrhosis cases are alcohol-induced, the separation of the effects of alcohol versus cirrhosis is virtually impossible.

On the other hand, nonalcoholic fatty liver disease (NAFLD) which is part of the metabolic syndrome, is associated with BPH in men and with overactive bladder in women (Uzun et al., 2013).

Hypertension

The sympathetic nervous system plays via alpha adrenergic fibers and receptors an important role in both hypertension and the symptoms of BPH. However, because both hypertension and LUTS/BPH increase with advancing age, it is difficult to prove a causal relationship between these two conditions (Boyle and Napalkov, 1995). The previously cited studies by Glynn et al. (1985) and Sidney et al. (1991) did not find an association. In a small-clinic cohort study with methodologic flaws, Pressler et al. (1997) reported an increase in the incidence of hypertension from 15%, to 18% and 31% for men with mild, moderate, and severe symptoms. Autonomic hyperactivity has been implicated in the development of both LUTS and ED in the aging male, but conclusive clinical data are lacking (McVary et al., 2005). In the EpiLUTS study, both heart disease and hypertension were associated with more severe LUTS symptom constellations (Coyne et al., 2009). Further studies are needed to better understand the common underlying pathophysiologic mechanisms and a potential cause-and-effect relationship.

Smoking

Smoking cigarettes appears to increase both testosterone and estrogen levels because of the nicotine level, and thus should have a positive and inductive effect on the development of BPH. However, because severe smoking causes other health problems, surgery rates are probably a poor indicator for a possible correlation because physicians are biased against surgery in heavy smokers. Seitter and Barrett-Connor (1992) indeed found no correlation between smoking and prostatectomy rates, and Glynn et al. (1985) failed to identify a correlation between smoking and the clinical diagnosis of BPH. Sidney et al. (1991a) followed 16,000 men over 15 years and found a negative correlation between being a smoker at baseline and subsequent risk for prostatectomy. Daniell (1993b) examined the records of 345 patients who underwent prostatectomy and found smaller gland volumes in smokers and a lower age-adjusted prevalence of never-smokers compared with a control group. Roberts et al. (1994a) examined this issue in the Olmsted County Study and later in a Japanese population (Roberts et al., 1997b). In Olmsted County, only 16% of the more than 2000 men were current smokers, which appears low but understandable considering the population mix in Rochester, Minnesota. A biphasic association was found, with light to moderate smokers being less likely to have moderate to severe LUTS, and heavy smokers being at least the same risk as never smokers.

A recent update from the Olmsted County Study suggests that smoking is associated with decreased urinary flow rates and moderate to severe symptoms, but not with enlarged prostate volume or increasing serum PSA (Rule et al., 2005). This is in contrast with earlier studies suggesting a relationship between smoking and prostate size (Kupeli et al., 1997). In EpiLUTS, ex-smokers had an increased risk for having more severe symptom constellations and never smokers a decreased risk, and the risk for current smokers was not a factor (Coyne et al., 2009).

Recent evidence from the Olmsted County Study verified the absence of a meaningful clinical association between current smoking and urinary retention (Sarma et al., 2009), and in the BACH study, no correlation between smoking and LUTS was observed (Maserejian et al., 2012).

In an exhaustive meta-analysis, Xu et al. (2016) found no significant association between cigarette smoking and BPH risk, either for ex-smokers or for current smokers.

Any relationships between current or past smoking and LUTS/BPH are likely to be weak and of limited clinical significance.

Physical Activity, Diet, Obesity, Body Mass Index, and the Metabolic Syndrome

Chyou et al. (1993) examined 33 food items in relationship to prostatectomy rates, and found only beef intake significantly associated. Araki et al. (1983) reported increased clinical diagnosis of BPH in men with higher milk consumption and lower consumption of green and yellow vegetables. **Overall, there is no convincing evidence for any individual diet factor to play a major role in the development of LUTS/BPH.**

The relationships between LUTS/BPH and obesity, body mass index (BMI), and the metabolic syndrome have recently been of great interest (Gupta et al., 2006; Hammarsten and Hogstedt, 1999, 2001; Hammarsten et al., 1998 Kasturi et al., 2006; Rohrmann et al., 2005). Metabolic syndrome is a clinical constellation of metabolic abnormalities, including obesity, glucose intolerance, dyslipidemia, and hypertension, that increases the risk for cardiovascular disease and results primarily from modifiable risk factors, particularly physical inactivity and dietary practices endemic to Westernized societies (Haffner and Taegtmeyer, 2003). **There are plausible biologic considerations: adipose tissue is the main source of aromatization of testosterone to estrogen, and men with lower BMIs have higher serum testosterone levels** (Eldrup et al., 1987).

BMI was negatively associated with surgically treated BPH in the Kaiser Permanente cohort study (Sidney et al., 1991a) and with a clinical diagnosis of BPH in the Normative Aging Study (Glynn et al., 1985). In contrast, in a study of 68 men, the average prostate weight increased both with age and with increasing obesity together with an increase in serum estradiol levels (Soygur et al., 1996). Daniell (1993a) also found larger adenoma in more obese men undergoing prostatectomy. Both latter studies report a positive correlation between obesity and prostate size, but none between obesity and symptom severity. Several caveats must be mentioned: DRE is less likely to yield a diagnosis of BPH and prostate enlargement in very obese patients because of anatomic obstacles, and patients with high BMIs may be biased against surgical interventions.

Men 40 to 75 years of age who were participants in the Health Professionals Follow-up Study and who were without prior diagnosis of cancer or prostatectomy provided data on weight, height, and waist and hip circumferences. After adjustment for age, smoking, and BMI, abdominal obesity was related to prostatectomy (OR, 2.38) and with frequent urinary symptoms among those without prostatectomy (OR, 2.00). BMI, hip circumference, and waist-to-hip ratio were not associated with BPH independently of waist circumference. **These results suggest that abdominal obesity in men may increase the frequency and severity of urinary obstructive symptoms and may increase the likelihood that such obese men will undergo a prostatectomy** (Giovannucci et al., 1994).

Hammarsten examined 250 patients with LUTS and found NIDDM, hypertension, height, obesity, high insulin, and low HDL cholesterol levels to be risk factors for the development of BPH. They suggest a causal relationship between high insulin levels and the development of BPH, and hypothesize increased sympathetic nerve activity in men with BPH (Hammarsten and Hogstedt, 1999). In a hospital-based case-control study, overweight was modestly inversely related to BPH. The hypothesis of reduced testosterone levels in obese individuals may explain the different BPH risk and needs to be tested (Zucchetto et al., 2005). Parsons (2007) performed a comprehensive literature review and found that factors that potentially increase the risk for BPH and LUTS include obesity and diabetes, and factors that potentially decrease the risk include increased physical activity and moderate alcohol consumption (Table 144.6). Parsons and Kashefi (2008) also performed a comprehensive literature review and found that eight studies (*n* = 35,675) were eligible for a pooled analyses to study the effect of physical activity levels stratified into light, moderate, and vigorous categories, with a sedentary category for reference. Compared with the sedentary group, the pooled ORs for BPH or LUTS were 0.70, 0.74, and 0.74 for men engaging in light, moderate, and heavy physical activity, respectively. Physical activity thus appears to reduce the risks for BPH and LUTS. Similar findings of increased likelihood of LUTS with increasing BMI and decreasing likelihood with greater physical activity were also reported from the EpiLUTS study (Coyne et al., 2009).

TABLE 144.6

Cohort Studies of Modifiable Risk Factor Associated With Decreased or Increased Risk for LUTS and/or BPH

DECREASED RISK FOR BPH AND LUTS			
STUDY	**OUTCOME MEASURE (RISK FACTOR)**	**REFERENCE CATEGORY**	**OR (95% CI)**
Health Professionals Follow-up Study	Clinical BPH:		

	Alcohol intake 30.1–50 g/day Walking ≥2 h/week	Alcohol intake 0 g/day	0.59 (0.51–0.70)
		Walking 0 h/week	0.73 (0.63–0.84)

	Diabetes	No diabetes	1.67 (0.72–3.86)
	Hypertension	No hypertension	1.76 (1.20–2.59)
	Increase in BMI between age 25 y + highest BMI ever	No increase	1.90 (0.89–4.05)
	Waist circumference >102 cm	Waist circumference <94 cm	1.48 (0.87–2.54)

BMI, Body mass index; *BPH,* benign prostatic hyperplasia; *CI,* confidence interval; *h,* hours; *LUTS,* lower urinary tract symptoms; *OR,* odds ratio; *TURP,* transurethral resection of the prostate.

From Parsons JK. Modifiable risk factors for benign prostatic hyperplasia and lower urinary tract symptoms: new approaches to old problems. *J Urol* 178(2):395–401, 2007.

The evidence at present suggests a positive relationship among lack of physical activity, obesity, BMI, and other measures of the metabolic syndrome and both LUTS and BPH (including prostate volume), and increased physical activity appears to have a protective effect.

Medications

Very limited information is available. **Cold medications containing α-sympathomimetic drugs exacerbate LUTS by the expected effect on the smooth muscles of the bladder outlet. Recently a careful analysis of the data from the Olmsted County Study demonstrated that daily use of antidepressants, antihistamines, or bronchodilators is associated with a 2- to 3-point increase in the IPSS compared with age-matched nonusers, and daily use of antidepressants is associated with a decrease in the age-adjusted flow rate** (Su et al., 1996).

Correlations Among Parameters

As noted, all relevant parameters such as symptom severity and frequency, bother, interference, disease-specific HRQoL, maximum flow rate, and prostate volume tend to worsen with advancing age. However, reported correlations between these parameters and urodynamic pressure-flow studies are in general weak with some exceptions. Strong correlations exist as one might expect between subjective measures such as symptom severity and frequency (IPSS), bother, disease-specific HRQoL, and interference scores (Barry et al., 1995c; Girman et al., 1999) (Fig. 144.15).

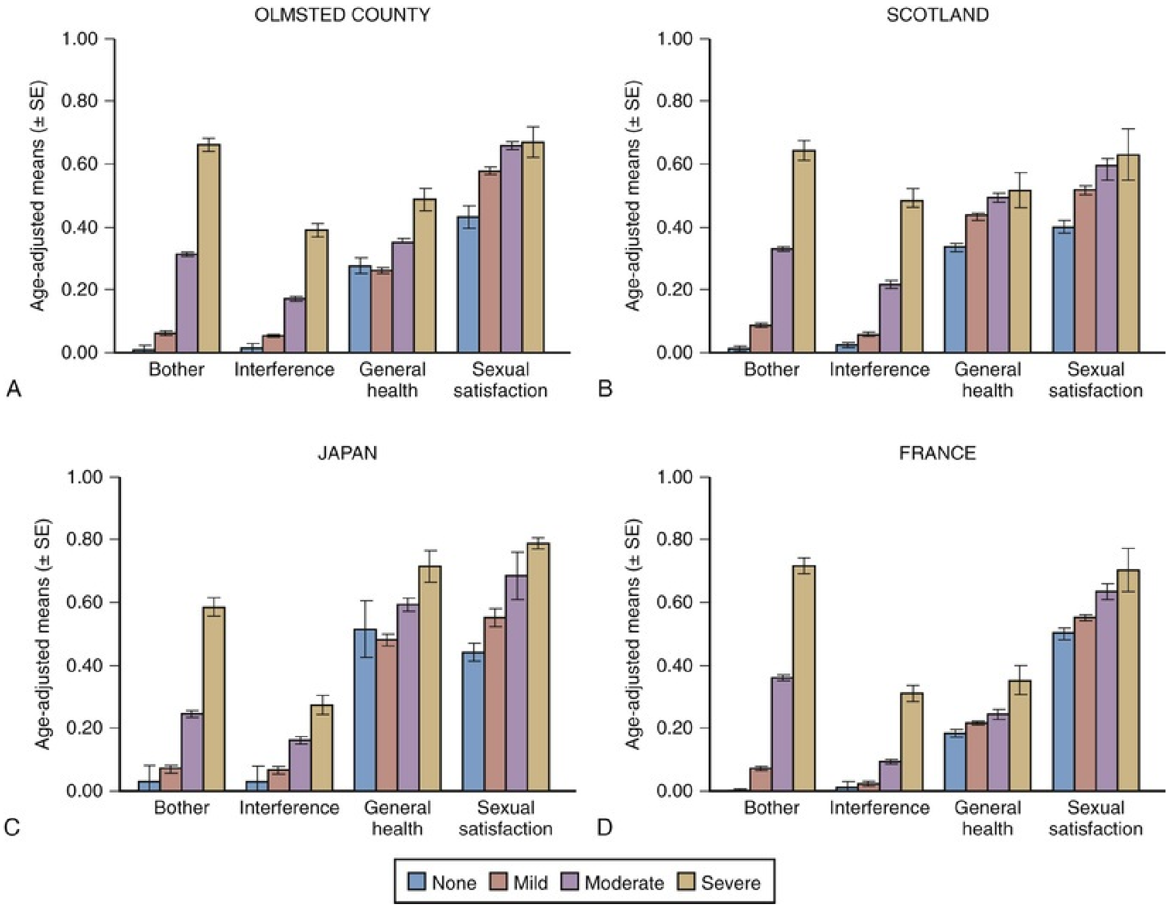

FIG. 144.15 (A–D) Age-adjusted means of disease-specific health-related quality-of-life measures after transformation to a 0 to 1 scale stratified by levels of symptom severity and frequency (International Prostate Symptom Score). (From Girman CJ, Jacobsen SJ, Tsukamoto T, et al. Health-related quality of life associated with lower urinary tract symptoms in four countries. *Urology* 51[3]:428–436, 1998.)

Weak numerical correlations can arise artifactually, regardless of whether true physiologic relationships exist (Girman et al., 1998). Correlations are further affected by intraindividual variability of measured parameters, day-to-day variability, measurement errors associated with the technique or equipment, or the natural history of the condition itself (Barry et al., 1995c; Bruskewitz et al., 1982; Diokno et al., 1992; Sagnier et al., 1996).

It is furthermore crucial to consider the population utilized to evaluate correlations. A correlation is easier identified if patients exhibiting the full spectrum of the parameters of interest are included. In most LUTS/BPH studies, however, patients are excluded based on thresholds imposed, making it more difficult for a significant correlation to emerge. There are many examples in clinical medicine in which weak numerical correlations exist, but strong clinical relationships are well-accepted (Wilson and Cleary, 1995).

The absence of meaningful baseline correlations for symptoms, flow rate, and prostate volume in a tightly controlled population of men with LUTS and BPH enrolled in a BPH treatment study is shown in Table 144.7.

TABLE 144.7

Correlation Table Among Baseline Parameters in a BPH Treatment Study of 2800 Men Older Than Age 50 Years, an IPSS >12, Peak Flow Rate (Qmax) <15 mL/sec, Serum PSA between 1.5 and 10 ng/mL, and TPV >30 mL (TZV Not Specified)[a]

	PSA	QMAX	IPSS	TPV	TZV
Age	0.092	−0.078	−0.069	0.152	0.154
	<0.0001	<0.0001	<0.0001	<0.0001	<0.0001

[a] Note the lack of strong correlations except for age and serum PSA versus volume among parameters.

BPH, Benign prostatic hyperplasia; *IPSS,* International Prostate Symptom Score; *PSA,* prostate-specific antigen; *TPV,* total prostate volume; *TZV,* transition zone volume.

An example of how restriction of the full range of parameters affects correlations is shown in Fig. 144.16. Volunteers without known prostatic diseases were asked to fill in an AUA symptom score (AUASS) and perform a flow rate. When all data are considered, a clear relationship exists with the maximum flow rate decreasing with increasing symptom severity ($r = 0.4$; $P < 0.05$). However, when only considering those patients typically seen in a BPH study, namely with a score above 10 points and a maximum flow rate between 5 and 15 mL/sec, the correlation within that cohort exhibiting a limited range of observation on both scales is very weak ($r = 0.08$; n.s.), and the regression line becomes flat (see Fig. 144.16).

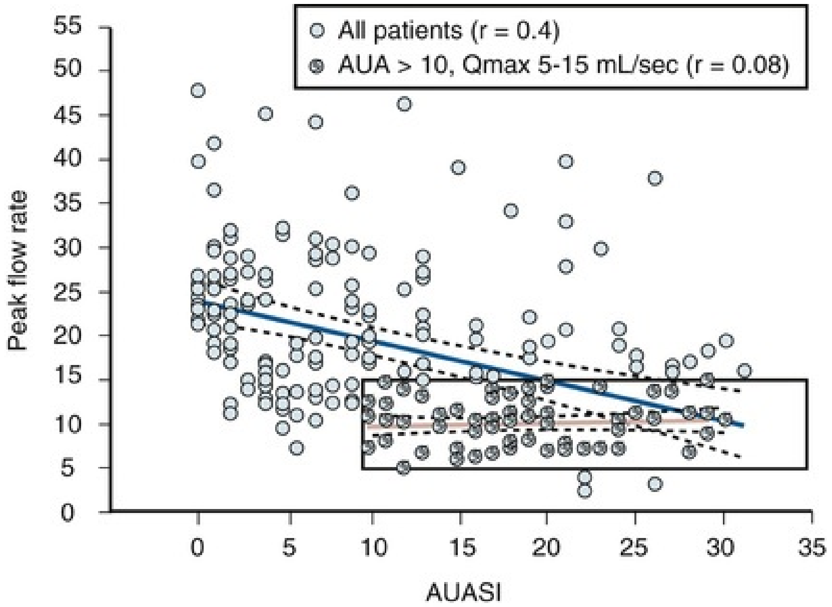

FIG. 144.16 Correlation and regression (95% confidence interval) between symptom score and maximum flow rate in volunteers ($r = 0.4$; $P < .05$). When only those volunteers are considered with a symptom score above 10 points and a flow rate between 5 and 15 mL/sec (◉), the correlation is virtually absent ($r = 0.08$; NS) as indicated by a flat regression line *(black). AUASI,* American Urological Association Symptom Index.

The correlations observed among symptoms, flow rate, and prostate volume in true community-based population studies without artificially imposed entry criteria are consequently somewhat higher than those seen in BPH clinic or trial populations. In the Olmsted County Study, after adjusting for age, the odds of moderate to severe symptoms were 3.5 times greater for men with prostatic enlargement (more than 50 mL) than for men with smaller prostates, and the odds were similarly increased (2.4-fold) for men not achieving a peak urinary flow rate of 10 mL/sec (Girman et al., 1995). Men with enlarged prostates were about twice as likely to have bother caused by symptoms (OR 2.4) or activity interference (OR 1.8) relative to men with smaller prostates (Girman et al., 1999). In a similar study from the Netherlands, Bosch et al. (1995) reported numerically weak but statistically significant correlations between the IPSS and total prostate volume ($r = 0.19$, $P < 0.001$), peak flow rate ($r = -0.18$, $P < 0.001$), and postvoid residual urine volume ($r = 0.25$, $P < 0.001$).

Although weak correlations between prostate volume and symptoms and flow rate have been accepted, recent attention has focused on correlations between the transition zone of the prostate and physiologic measures. A stronger correlation between transition zone and symptoms ($r = 0.48$, $P = 0.03$) and peak urine flow ($r = -0.34$, $P = 0.05$) was reported first by Kaplan et al. (1995), who also showed a significant correlation between transition zone index (TZV/TPV) and symptoms ($r = 0.75$), peak urine flow ($r = -0.71$), and—somewhat unexpectedly—detrusor pressure at peak urine flow ($r = 0.43$). These data were generated from a relatively small cohort of 61 men with BPH. Invasive pressure-flow studies are not performed in community-based studies, and thus comparative data from population-based studies cannot be reviewed. However, the finding of a relationship between measures of obstruction and prostate volume is rare, with most authors denying such a relationship in series of BPH clinic or trial patients (Bosch et al., 1995; d'Ancona et al., 1998; Ezz el Din et al., 1996; Homma et al., 1998; Kuo, 1999; Steele et al., 2000; Witjes et al., 1997; Yalla et al., 1995). Data from the Olmsted County Study suggest no stronger correlation between symptoms and peak flow rate with transition zone volume ($r = 0.17$, $P = 0.001$ and $r = -0.20$, $P<0.001$, respectively) than with total volume ($r = 0.16$, $P < 0.001$ and $r = -0.16$, $P < 0.001$, respectively). The transition zone index weakly correlated with AUA symptom index ($r = 0.08$, $P = 0.103$) and peak urinary flow rate ($r = -0.08$, $P = 0.0823$) (Corica et al., 1999). In a large BPH treatment trial, correlations between transition zone and other measures were no better than the correlations between total prostate volume and those same measures.

The correlation between serum PSA and prostate volume, both total and transition zone, has been described in greater detail (Roehrborn et al., 1999a). Although the individual variability is significant, precluding an accurate prediction of prostate volume by serum PSA in individual patients, there is a strong log linear relationship between these parameters that can be shown in both population-based and clinical studies (Hedelin et al., 2005; Hochberg et al., 2000; Morote et al., 2000). The relationship is further influenced by patients' age, with older patients having a greater increase in prostate volume per unit of serum PSA (Fig. 144.17). In Asian men, similar relationships exist, however, in general both prostate volume and serum PSA tend to be smaller/lower (see Fig. 144.17B) (Gupta et al., 2005). Relationships between other PSA-derived parameters have recently been examined, and certain subforms of PSA (BPSA) has been shown to be stronger related to BPH compared with total serum PSA (Canto et al., 2004).

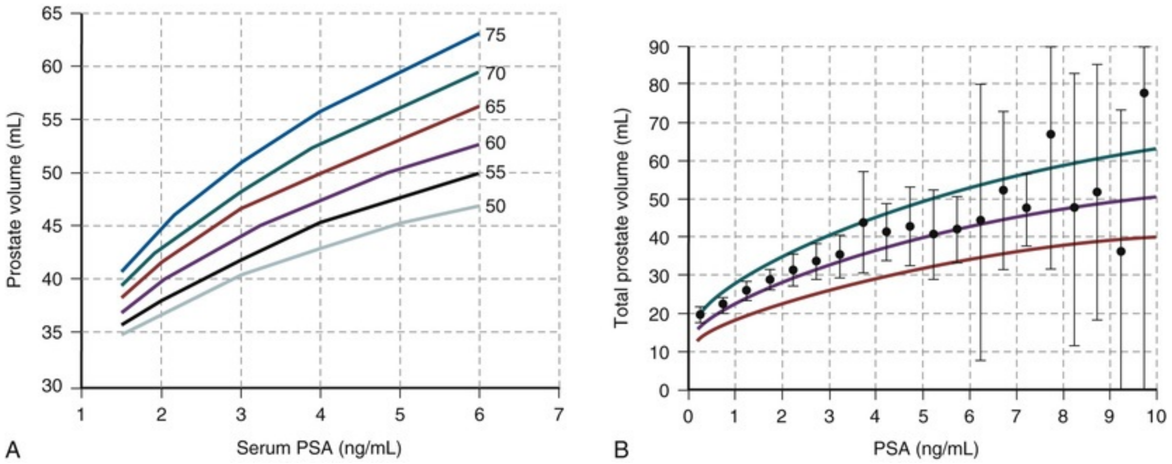

FIG. 144.17 Prediction of prostate volume based on serum prostate-specific antigen *(PSA)* stratified by age in white men (A) and in Japanese men (B). (A, From Roehrborn CG, Boyle P, Gould AL, Waldstreicher J. Serum prostate-specific antigen as a predictor of prostate volume in men with benign prostatic hyperplasia. *Urology* 53[3]:581–589, 1999c. B, From Gupta A, Aragaki C, Gotoh M, et al. Relationship between prostate specific antigen and indexes of prostate volume in Japanese men. *J Urol* 173[2]:503–506, 2005.)

With the exception of age, correlations between various measures of LUTS and BPH are modest in community-based population studies and weak in BPH clinic and trial populations. The relationship between serum PSA and prostate volume is moderate and influenced by age and race and ethnic origin. Neither symptoms nor flow rate nor prostate volume measures can predict presence and degree of obstruction reliably.

Natural History of Untreated Benign Prostatic Hyperplasia

The natural history of a disease process refers to the prognosis of the disease over time. In other words, the measurement of changes in parameters of interest and the incidence rates of significant outcomes constitute what is commonly referred to as the “natural history” of a disease. It is important for clinicians to gain as good an understanding as possible of the natural history of any illness, because the benefits and risks associated with any therapeutic interventions should always be balanced with the risks involved in just watching the disease (i.e., the natural history). In fact, the degree to which natural history must be studied depends on the seriousness of the disease and the risks involved with the therapeutic intervention. For example, it proves to be crucial to understand the natural history of abdominal aortic aneurysms and how their prognosis is determined by their size to adequately counsel patients regarding surgical interventions, which have considerable risks in themselves.

Clinical Parameters and Outcomes of Interest

Table 144.8 lists the beneficial and harmful changes in measurable parameters and outcomes, which are of interest in both the natural history and treatment of LUTS and BPH. They may be divided further into direct or biologic and indirect or proxy outcomes (Eddy, 1990, 1992). The biologic or direct outcomes are those that are immediately noticeable by the patients (e.g., symptom changes, infections, death), and the indirect or proxy outcomes are not directly noticeable, but may predict future changes in direct outcomes (e.g., changes in pressure flow parameters may predict episode of retention). The parameters and outcomes are dichotomous (yes or no, e.g., retention or no retention), categorical (grades of severity, e.g., grades of obstruction measured by pressure-flow studies), or continuous (scales of severity, e.g., symptom score, maximum flow rate). Accordingly, the most common ways to measure such outcomes are probabilities or rates of occurrences for dichotomous or categorical outcomes, and measures of central tendency (mean or median) and variability (standard deviation [SD] or standard error [SE] or confidence intervals [CIs]) for outcomes measured by continuous scales.

TABLE 144.8

Beneficial and Adverse Changes in Parameters and Outcomes

BENEFICIAL CHANGES		**HARMFUL CHANGES**	
Probability of symptom improvement	D	D	Probability of symptom worsening
Magnitude of symptom improvement	D	Co	Magnitude of symptom worsening
Magnitude of bother improvement	D	Co	Magnitude of bother worsening

Methods of Studying Natural History of Benign Prostatic Hyperplasia

The natural history of BPH can theoretically be evaluated by studies of a variety of designs:

Longitudinal studies of untreated cohorts of men diagnosed with LUTS and clinical BPH by any definition *(watchful waiting cohorts).*

- Studies of the behavior of men diagnosed with LUTS and BPH and enrolled in controlled studies of LUTS and BPH *(control groups)* and receiving one of the following:
  - *no treatment* (compared with active intervention)
  - *placebo* treatment (compared with medical treatment)
  - *sham* treatment (compared with device or surgical treatment)

Longitudinal studies of unselected (i.e., undiagnosed) men living in the community who are less likely to progress and request or require therapy *(longitudinal population-based studies).*

There are problems associated with either of the approaches. Concerning the *watchful waiting cohorts,* the first question to be resolved is whether or not it is ethical (or feasible) to enroll symptomatic men in such a study, even if the disease studied is not fatal. Secondly, the very fact that the patients had initial and presumably subsequent contact with health care providers in the course of the study will bias them, leading to changes in outcome parameters of interest presumably different from those observed in an age-matched cohort of men who were similar in all parameters at baseline but did not choose to participate (a cohort one might call in analogy to genetic language “wild type”). Further, many diagnosed men will in the course of such natural history study become more and more symptomatic and desire and receive treatment, making them ineligible to further participate in the study, thus reducing the number of men available for analyses. Lastly, a very important bias is introduced by the fact that patients in such cohorts are selected based on thresholds imposed by inclusion and exclusion criteria. In general, patients are selected to participate who are more symptomatic (i.e., those with higher symptom scores and lower maximum flow rates). By the principle of trial conduct, patients then repeat the symptom and flow rate assessment during follow-up (or after treatment). However, the same inclusion/exclusion criteria are not applied to the follow-up measurements, which leads to a unilateral regression to the mean, suggesting (falsely) an improvement in the parameter of interest.

To determine the effect that the stringency of pretrial screening has on the outcome of placebo treatment, a cohort of 145 volunteers were invited to fill in the IPSS and perform a flow rate recording twice within 1 month without receiving any therapy or instructions whatsoever (Sech et al., 1998). Although many patients experienced either an increase or a decrease in both parameters, the mean values did not change significantly (IPSS 12.1 vs. 11.7 points, peak flow rate 17.7 vs. 17.4 mL/sec; not significant). However, when typical BPH trial conditions were applied and only those patients considered for analyses who had an IPSS above (>7, >10, >15) and a flow rate below a certain threshold (<15, <12, <10 mL/sec), a unilateral regression to the mean took place, by which the more symptomatic volunteers (i.e., patients) experienced still considerable natural variability on the second assessment, but the net effect was toward “improvement” (i.e., lower scores and higher flow rates). For example, when only considering patients with IPSS greater than 10 points, the mean difference between the first and second assessment was between 19.9 versus 18.8 points, or –1.1 (*P* < 0.05). Similarly, when only patients with a peak flow rate less than 12 mL/sec were considered, the mean difference between the first and second assessment was 9.3 versus 10.9 mL/sec, or +1.6 mL/sec (*P* < 0.01) (Table 144.9).

	No. 2	20.6 ± 6.6	0–32	−2.8 to 0.01		

[a] Statistical comparison between test No. 1 and No. 2 by T-test.

Note the reduction in the number of patients available for follow-up because of censoring that affects the power of the statistical test.

From Sech SM, Montoya JD, Bernier PA, et al. The so-called “placebo effect” in benign prostatic hyperplasia treatment trials represents partially a conditional regression to the mean induced by censoring. *Urology* 51(2):242–250, 1998.

This experiment clearly illustrates that a unilateral regression to the mean induced and controlled by the stringency of the inclusion criteria can result in a significant “improvement” in any parameter for which a threshold is set at the baseline screening. Such purely mathematical effect is likely at work in many if not all studies in which the outcome parameters are measured using a numerical scale of some sort, and where baseline screening criteria are applied.

Control groups of men being randomized to receive no treatment, placebo, or sham treatment, while being compared with a matched group of men receiving active therapeutic interventions also suffer from a variety of biases. As the *watchful waiting cohorts*, they have initial and constant contact with health care providers, they know from the design of the study that they are randomized to the perceived less effective or ineffective arm, and thus they may have a lower threshold than community-dwelling men to cross over to active therapy. On the other hand, because of a sense of obligation, they may elect to be followed until the trial is over and then choose an active treatment. They are also subject to regression to the mean bias discussed earlier, because they were subjected to inclusion/exclusion criteria.

***Longitudinal population-based studies*, although difficult and expensive to conduct, are likely the best vehicle to understand the natural history of the disease.** The regression to the mean bias does not apply, as the participants are not selected based on inclusion and exclusion thresholds. Because no formal diagnosis is established, the natural history may take place unencumbered by preconceived notions about symptoms, endpoints of trials, and anything else leading to a bias in a watchful waiting cohort of diagnosed and thus labeled men or in a control group of diagnosed men. One must realize, however, that the very need to monitor the natural history (i.e., the need to ask questions, perform tests and intervention) conflicts with the notion of “natural history,” and thus some biases are likely to be unavoidable, even in the most ideal setting.

Watchful Waiting Studies

In the past, some investigators have attempted to conservatively follow cohorts of men diagnosed with LUTS and/or BPH *(watchful waiting cohort)*, but the few published reports are of limited scientific rigor and informational value, and they have significant shortcomings. Inclusion and exclusion criteria are poorly defined, follow-up and compliance are poor, assessment instruments are either not defined or insufficient, and patient accounting is incomplete. The studies provide answers regarding the probability of symptom changes and the magnitude of flow rate changes.

Five such studies were reported between 1919 and 1988, with a total

enrollment of 456 patients and a follow-up ranging from 3 to 6 years (Ball et al., 1981; Birkhoff et al., 1976; Clarke, 1919; Craigen et al., 1969; Kadow et al., 1988). A change in symptom status was reported for all 456 patients, and none of the studies utilized a quantitative symptom severity scale. Data on urinary flow rate and residual urine were available for 223 and 197 patients, respectively. The peak urinary flow rate deteriorated in 66% and improved in 20%. Residual urine increased (35%), decreased (37%), and remained unchanged (28%) in about the same number of all patients. The mean change in peak flow rate (in those patients for whom data are available) was +2.2 mL/sec (from a mean of 9.0 to 11.2) or 24%, and the mean change in residual urine was +37 mL (from a mean of 115 to 152) or 32%. Data on symptom improvement were reported as a dichotomous outcome (improved versus not improved). **The mean probability for any improvement in symptom severity in these studies is 42.5% (90% CI 30.8 to 54.8) as calculated by meta-analytical methods** (Eddy and Hasselblad, 1992).

Wasson et al. (1995) **chose a superior approach, namely to follow a *no-treatment control group* of men diagnosed with LUTS and BPH. A total of 556 men with moderate symptoms and a Madsen-Iversen symptom score between 10 and 20 points (0- to 27-point scale) were randomized to either undergo transurethral resection of the prostate (TURP) or be watched conservatively.** There were 47 treatment failures (defined as death, recurrent infection, residual urine volume over 350 mL, development of bladder calculus, incontinence, symptom score of 24 or higher, or doubling of serum creatinine from baseline) in the watchful waiting arm ($N = 276$) versus 23 in the surgery arm ($N = 280$) over a 3-year follow-up (relative risk 0.48; 95% CI, 0.3 to 0.77). Sixty-five men (24%) assigned to watchful waiting underwent surgery during follow-up, 20 of them for treatment failure. The majority of these men were classified as more bothered at baseline, and about 40% of patients in this category experienced an improvement in the degree of bother from urinary difficulties, a proportion strikingly similar to the overall estimate of 42.5% from the natural history studies. At 3 years of follow-up, the patients randomized to watchful waiting who did not fail or cross over to surgery had a small but noticeable improvement in nearly all outcomes measured, including a +0.4 mL/sec increase in the maximum flow rate. In 1998, a 60-month update was reported providing data on 966 patient-years of follow-up on the TURP and 990 patient-years on the watchful waiting patients (Flanigan et al., 1998). The treatment failure rates were 21% for the watchful waiting group and 10% for the

TURP group, and all outcomes were better for the TURP treated patients (Table 144.10). During follow-up, 76 watchful waiting patients (27%) crossed over to TURP; the 5-year Kaplan Meier estimate of the crossover rate was 36%; and twice as many patients crossed over electively as compared with post-treatment failure protocol–dictated crossover. **The most significant factor predicting elective crossover was high baseline bother caused by urinary symptoms** (Fig. 144.18). When separately analyzed, the patients' crossing over from watchful waiting to TURP had fewer improvements in outcome parameters compared with those randomized to TURP initially (Table 144.11). In many instances, the differences between the groups were statistically and clinically significant. A reduction in symptom score by –11 points (high baseline symptom group) and an improvement in maximum flow rate by 8.7 mL/sec (low baseline flow rate group) after TURP is expected; however, the improvements were only –8 points and +4.7 mL/sec in men undergoing TURP after an unsuccessful trial of watchful waiting. **This allows the speculation that during the period of watchful waiting before crossover, some irreversible damage might have occurred preventing symptom and flow rate improvements to the same level as observed in those men initially treated by TURP.**

Djavan et al. (2004) followed a group of 397 men presenting to a urology clinic with mild LUTS, defined as scoring less than 8 points on the IPSS. These men were followed for 4 years beginning with a watchful waiting protocol and were reevaluated every 3 months for 48 months total time. The cumulative incidence of clinical progression, defined as worsening of the IPSS with migration from mild to moderate (IPSS 8 to 18 points) or severe symptoms (IPSS 19 to 35 points) was assessed. The likelihood of migrating or transitioning from one health state to another was 6%, 13%, 15%, 24%, 28%, and 31% at 6, 12, 18, 24, 36, and 48 months, respectively.

Placebo and Sham Control Groups in Randomized Trials

Data from *control groups treated with placebo or sham* and compared with matched groups of patients treated with medications or devices are available to address many of the parameters and outcomes of interest.

Placebo Control Groups.

For the Guidelines for the Diagnosis and Treatment of BPH published by the Agency for Health Care Policy and Research in 1994, data on 1417

patients treated in 45 placebo arms of placebo-controlled trials were analyzed (McConnell et al., 1994). Table 144.12 **allows a direct comparison between the watchful waiting studies discussed earlier and these placebo groups, both summarized by meta-analytical techniques.** For none of the examined parameters, a significant difference between the two treatment modalities can be identified. However, several points deserve discussion. As opposed to the longer-term follow-up in the watchful waiting studies, the placebo studies are part of short- to mid-term medical treatment trials ranging from 3 days to 52 weeks in duration (mean 13 weeks). In all of these studies, the patients are blinded as to the treatment arm, and thus have in most cases at least a 50 : 50 (or better in case of 2 : 1 or 3 : 1 randomization) chance of receiving active drug. Dropping out of such studies because of failure does not have the same ramification as in watchful waiting studies, where the patients willingly assumed a conservative treatment approach knowing that it might fail (i.e., they might fail and go on to active treatments). In contrast, in some placebo-controlled studies a promise (either tacit or openly) is made stating that after the conclusion of the trial, the patient would be eligible for either "free" active treatment or would be "moved up" on the surgical waiting list (this phenomenon is unique to those studies conducted in the United Kingdom). The inactive preparation given should theoretically add to the placebo effect and thus improve the outcome above those noted for watchful waiting studies. The probability for a patient to experience improvement, however, is estimated to be about 40% in the uncontrolled watchful waiting studies, the randomized watchful waiting versus TURP study, and the combined placebo arms. The changes in peak flow rate and residual urine are similar, and similarly small, for these three groups as well. **It becomes evident that 40% of patients report some improvement, and the minimal fluctuation of peak flow rate and residual urine represent the "placebo effect" background against which the more substantial changes in these parameters achieved by active treatment modalities must be seen.**

TABLE 144.12

Comparison of Outcomes After Watchful Waiting and Placebo Treatment

OUTCOME	WATCHFUL WAITING	PLACEBO
Total number of patients	456	1417

Probability for flow rate increase	19.7%	35.8%
Probability for no change in flow rate	14.2%	41.1%
Probability for flow rate decrease	66.1%	23.1%
Mean pre- and post-treatment flow rate (mL/sec)	9.0–11.2	9.1–9.7
Difference (mL/sec) and percent change	+2.2/+24.4%	+0.6%/+6.6%
Probability for decrease in residual urine	35.0%	38.0%
Probability for residual urine to remain unchanged	28.0%	26.1%
Probability for increase in residual urine	37.0%	35.9%
Mean pre- and post-treatment residual urine (mL)	115–152	87–76
Difference (mL) and percent change	+37/+32.2%	−11%/−12.6%
Probability for symptom improvement	41.7%	41.7%
Probability for symptoms to remain unchanged	25.8%	53.5%
Probability for symptom worsening	32.4%	4.7%
Mean probability for symptom improvement[a]	41.7%	41.7%
90% CI for symptoms improvement[a]	30.8–54.8%	26.3%–65.1%

[a] Calculated by confidence profile method using hierarchical Bayes (Eddy and Hasselblad, 1992).

CI, Confidence interval.

Sham Control Arms of Device Treatment Trials for BPH.

In recent years, a multitude of minimally invasive device treatments for BPH have been developed and tested in randomized, sham-controlled, open, single-, or even double-blind trials. Although the majority of these trials compare various types of heat treatments (transrectal or transurethral hyperthermia or thermotherapy) with a sham treatment, one investigator compared balloon dilation with “sham” cystoscopy alone in a randomized, double-blind trial involving 33 men with BPH (Lepor et al., 1992b).

The outcomes of the balloon dilation versus cystoscopy trial, one multicenter trial using transrectal or transurethral hyperthermia in comparison with a sham control (Abbou et al., 1994), and five transurethral microwave thermotherapy (TUMT) trials and their respective sham control arms can be used for analyses (Bdesha et al., 1994; Blute et al., 1993; de la Rosette et al., 1994; Ogden et al., 1993). Although the mean pretreatment severity score differs from trial to trial, the mean improvements in symptom severity in the sham groups ranged from 5.2% to 15.6% (on a 100% scale), and the active thermotherapy treated patients had improvements ranging from 27.0% to 37.8%, or in most cases twice the improvement as the sham control. The multicenter hyperthermia trial represents the exception, in that the actively treated cohort has an improvement similar to the sham control, which is well within the range of the other sham control trials. The changes in peak urinary flow rate follow a similar pattern. With few exceptions, the changes in peak flow rate are either very modest improvements or deteriorations (0.5, 0.6, –0.2, –1.0 mL/sec), and the active treatment arms report substantial improvements, with the exception of the hyperthermia trial.

Placebo/Sham Effect and Baseline Symptom Severity.

An area of considerable interest is the question to what degree the placebo/sham effect depends on the baseline status of the patients. This could pertain to baseline symptom severity, baseline bother, quality of life, baseline flow rate, and all other imaginable parameters. Although few investigators have thus far reported data stratified by baseline parameters, results from a multicenter, placebo-controlled, 12-month α-blocker trial (terazosin) can be analyzed (Roehrborn, 1996). Although the active drug-treated cohort has almost twice the improvement within each stratum, the placebo-treated patients had improvements ranging from 1.4 points (4.6%) to 7.5 points (21.4%) in order of increasing baseline severity score. The placebo improvements for the placebo cohort overall was 3.3 points (10.6%).

A similar increase in the placebo effect with increasing baseline symptom severity has been reported for patients treated with finasteride in the phase III trials (Gormley et al., 1992). It might be speculated that the baseline symptom severity may also affect the sham effect seen in device trials. **This phenomenon might be caused by increased expectations in patients with more severe baseline symptoms or simply caused by a regression to the mean.**

Natural History and Disease Progression in Long-Term Placebo Arms.

The distinction between changes in parameters and rates of outcomes observed in *placebo and sham control groups* versus the *longitudinal population-based studies* becomes blurred when the placebo control is carried out over a period long enough to allow natural history changes to

take place and confound the situation.

The Proscar Long Term Efficacy and Safety Study (PLESS) followed a cohort of over 3000 men with moderate symptoms and enlarged prostate glands randomized to treatment with finasteride 5 mg daily versus placebo over 4 years (McConnell et al., 1998). In most control arms, both placebo and sham, the combined placebo effect interfering with the natural history of the disease is maintained for the entire duration of the study. In this 4-year trial, however, both the mean symptom score and mean maximum flow rate slowly drifted back to baseline after a typical initial placebo response (McConnell et al., 1998). The changes occurring in measurable parameters after the initial placebo effect has taken place thus can be considered to represent the natural history of the disease. The rates of outcomes such as AUR or surgery, and changes in prostate volume, which are less or not at all susceptible to the placebo effect, are also valid measures of the natural history of the disease.

The almost 1500 men in the placebo arm of this trial allowed for a detailed analysis of the placebo response and the subsequent natural history stratified by baseline parameters. It had been shown that in men with BPH, there is a relatively strong correlation between prostate volume and serum PSA. In the PLESS, only 10% of patients underwent baseline and yearly volume measurements by endorectal coil MRI. Based on the assumption that serum PSA would be a good proxy parameter for prostate volume, the analysis was initially performed for serum PSA and based on all 1500 men treated with placebo.

When stratifying the population by serum PSA into tertiles or thirds of patients with PSA levels from 0 to 1.3, 1.4 to 3.2, and 3.3 to 10 ng/mL, three distinctly different patterns regarding symptom score and maximum flow rate changes emerge (Fig. 144.19) (Roehrborn et al., 1999a). Although the initial placebo response in the lowest PSA tertile for both symptom and flow rate was maintained over the entire 4 years of follow-up, the middle tertile experienced a slow deterioration of symptoms back to baseline, and in essence the natural history and progression of disease negated any flow rate gains. In the highest PSA tertile, the symptom score increased steadily over time after an initial placebo response by –1.5 points. Over the subsequent years, the score increased by 0.5 points per year, bringing it back to the original baseline level at the end of the study. The initial response in terms of flow rate improvement was completely negated by the progression/natural history after 2 years, and at the end of the study, this group of patients registered a net worsening of the flow rate by a mean of –1.0 mL/sec (see Fig. 144.19B). Similar results regarding changes in symptom and maximum flow rate over time were obtained when the 150 patients for whom prostate volume measurements were available were divided into tertiles (14 to 41 mL, 42 to 57 mL, 58 to 150 mL). The PLESS also assessed periodically bother caused by urinary symptoms, disease-specific quality of life, aspects of sexual function, and overall sense of well-being. Surprisingly, serum PSA at baseline also predicts after an initial placebo response the rate of deterioration of bother, quality of life, and certain aspects of sexual function (Bruskewitz et al., 1999) (Fig. 144.20).

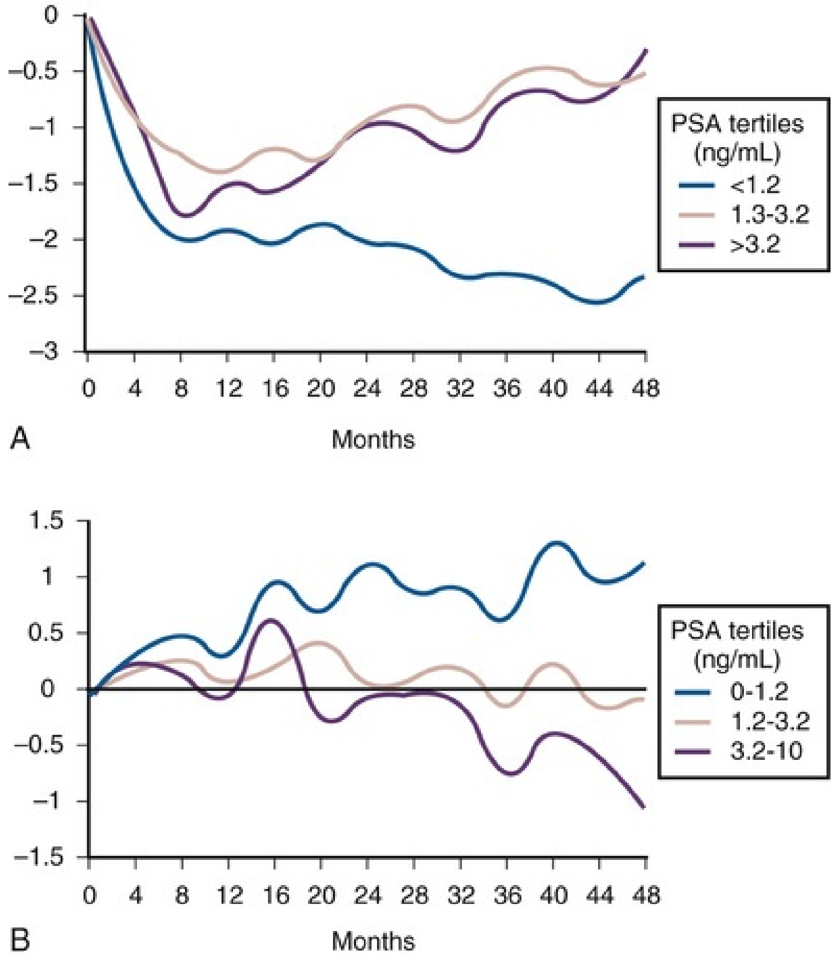

FIG. 144.19 Mean changes for symptom (A) and peak flow rate (B) in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study stratified by baseline serum prostate-specific antigen *(PSA)* levels. (From Roehrborn CG, Boyle P, Gould AL, Waldstreicher J. Serum prostate-specific antigen is a reliable surrogate for prostate volume. *Urology* 53[3]:581–589, 1999c.)

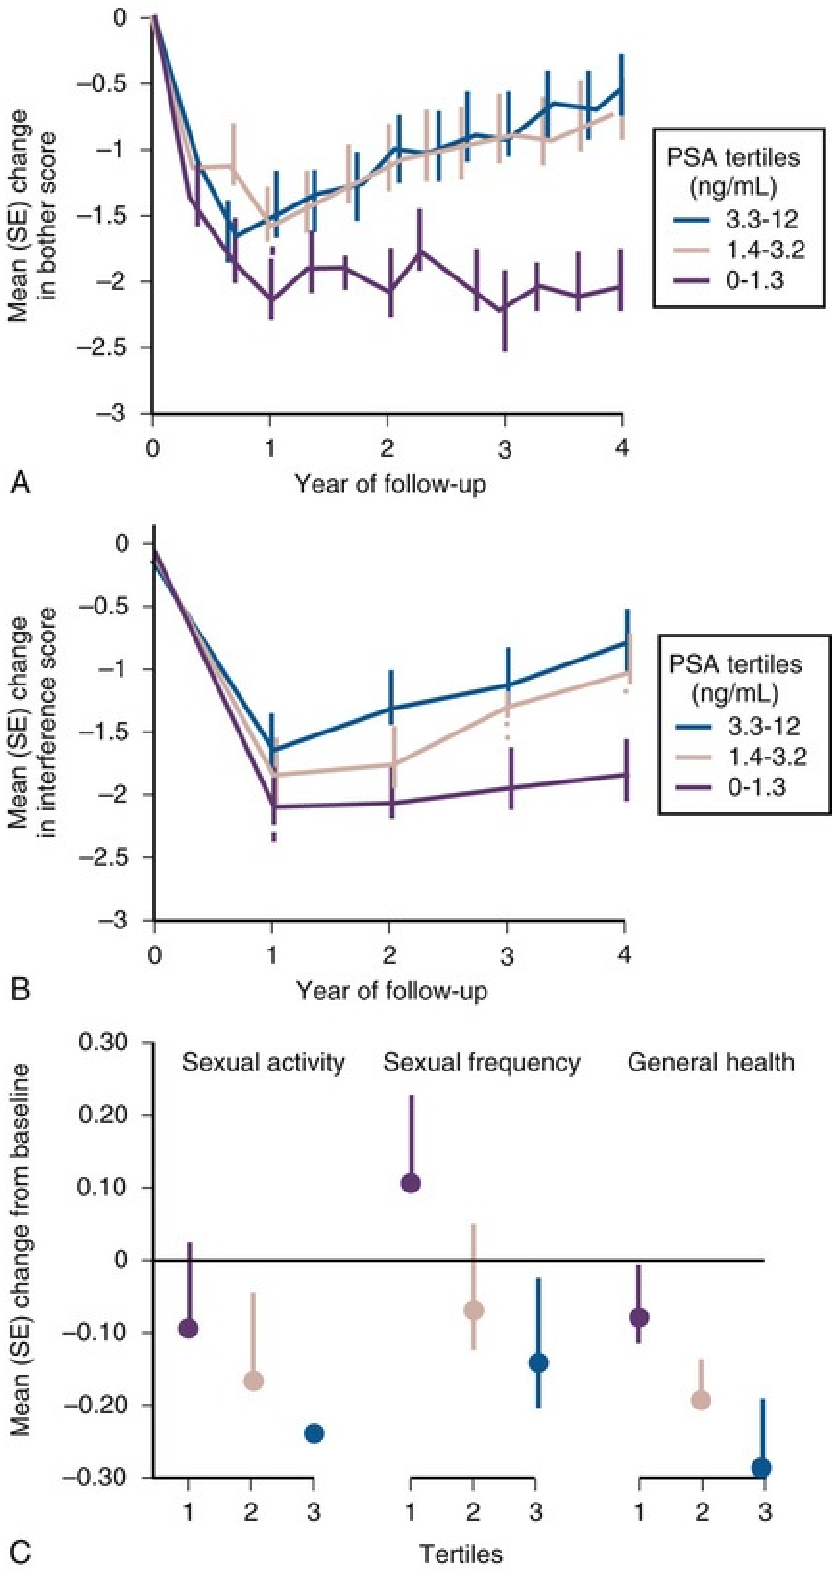

FIG. 144.20 Mean changes for bother (A), interference with activities of daily living (B), and for sexual activity, frequency, and perception of general health (C) in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study stratified by baseline serum prostate-specific antigen *(PSA)*

levels. *SE,* Standard error. (From Bruskewitz R, Girman CJ, Fowler J, et al. Effect of finasteride on bother and other health-related quality of life aspects associated with benign prostatic hyperplasia. PLESS Study Group. Proscar Long-term Efficacy and Safety Study. *Urology* 54[4]:670–678, 1999.)

The Medical Therapy of Prostatic Symptoms (MTOPS) study followed 3045 men treated with either placebo versus doxazosin versus finasteride versus combination therapy for 4 to 5 years and was designed as a progression study (Bautista et al., 2003; McConnell et al., 2003). The composite endpoint captured either a worsening of greater than or equal to 4 points on the IPSS verified twice within 4 weeks, AUR, socially unacceptable incontinence, recurrent urinary tract infection (UTI), or renal insufficiency caused by BPH (Table 144.13). The greater than or equal to 4 points worsening was chosen to reflect a clinically meaningful worsening of LUTS symptomatology. Despite an overall numerical improvement in the IPSS by –4.9 points in the placebo group (intention to treat cohort), about 14% of placebo-treated patients experienced a verified worsening by greater than or equal to 4 points over the course of the study for an incidence of 3.6/100 patient-years (see Table 144.13).

TABLE 144.13

Clinical Progression of BPH in Placebo-Treated Patients in MTOPS

EVENT	RATE OVER DURATION OF STUDY	CUMULATIVE NUMBERS OF EVENTS AT 4 YEARS	CUMULATIVE INCIDENCE (95% CI) AT 4 YEARS
Clinical progression overall	4.5	122	17 (14–20)
≥4 points IPSS increase	3.6	97	14 (11–17)
Acute urinary retention	0.6	18	2 (1–4)
Socially unacceptable incontinence	0.3	6	<1 (0–1)
Urinary tract infections	0.1	1	<1 (0–1)
Renal insufficiency	0.0	0	0

caused by BPH			
Invasive therapy caused by BPH	1.3	37	5 (3–7)

Recently, two separate post-hoc analyses of the prostate cancer prevention trial REDUCE were published shedding light on the natural history of the interrelationship between prostate size and development of LUTS (Simon et al., 2016). Among men treated with placebo during the REDUCE study, those with a prostate size of 40 to 80 mL had a 67% higher risk (hazard risk 1.67, 95% CI, 1.23 to 2.26, $P = 0.001$) for developing incident LUTS compared with men who had a prostate size of 40 mL or smaller. The second analysis focused on the urinary flow rate parameters and showed in univariable analysis when peak flow was categorized as 15 mL/sec or greater, 10 to 14.9 mL/sec, and less than 10 mL/sec, flow rates of 10 to 14.9 mL/sec and less than 10 mL/sec were associated with a significantly increased risk for incident LUTS (hazard ratio [HR] 1.39, $P = 0.011$ and 1.67, $P<0.001$, respectively) (Simon et al., 2017).

The placebo control groups of large studies such as the PLESS and the MOTPS allow the study of natural history and disease progression in a cohort selected for moderate symptoms and other evidence of disease (in contrast with a population-based study) on the background of the initial placebo responses. In the MTOPS, approximately 14% of placebo-treated patients experienced a greater than or equal to 4-point worsening in the IPSS over 4 years of follow-up. REDUCE as a prostate cancer prevention trial does not suffer from the placebo effect and demonstrated prostate size and peak urinary flow rate to predict future development and diagnosis of LUTS.

Relationship Between Placebo/Sham Effect and Perception of Improvement.

Barry et al. reported an important observation by assessing the relationship between changes in the AUA symptom index and patients' global rating of improvement in over 1200 men treated in a medical treatment trial for BPH

(Barry et al., 1995d). **They noted that a mean decrease in AUA symptom index of 3.1 points was associated with a slight improvement; however, this relationship was strictly dependent of the baseline AUA symptom index. For patients to perceive a slight, moderate, or marked improvement, increasing drops in AUA symptom index were required with increasing baseline symptom severity.** For patients starting with a lower versus higher baseline score, the drop had to be –7.4 versus –15.3 points, respectively, to perceive a marked improvement; –4.0 versus –8.7, respectively, for a moderate improvement; –1.9 versus –6.1, respectively, for a slight improvement; –0.2 versus –2.0, respectively, for no improvement; and +3.3 versus +1.2, respectively, for worsening.

Longitudinal Population-Based Studies.

Diokno et al. (1992) **provided estimates of the prevalence, incidence, and remission of LUTS in 803 community-dwelling men 60 years of age or older.** The annual incidence of prostate surgery was 2.6% and 3.3% during years 1 and 2 of follow-up, respectively. The prevalence of at least one symptom was 35%, with annual incidence rates of 16.4% and 16.1% during years 1 and 2 of follow-up, respectively. Remission was also noted in that 22.9% of those having severe symptoms at baseline were asymptomatic at follow-up. Table 144.14 details the changes in symptom severity from one survey to the next. **The tendency for fluctuation and spontaneous remission of symptoms and the regression to the mean become evident from an analysis of these data.**

TABLE 144.14

Changes in Status of Symptom Severity From One Survey to the Next[a]

SEVERITY	YEAR	NO. PATIENTS	SEVERITY IN FOLLOWING YEAR (%)			
			NONE	MILD	MODERATE	SEVERE
None	Baseline	293	83.6	12.3	2.7	1.4

[a] Patients who underwent prostatectomy in the preceding year were excluded from the next survey.

Modified from Diokno AC, Brown MB, Goldstein N, Herzog AR. Epidemiology of bladder emptying symptoms in elderly men. *J Urol* 148(6):1817–1821, 1992.

Garraway et al. conducted a study of LUTS in four villages in the Forth Valley in Scotland in men 40 to 79 years of age defining BPH as a prostate volume of over 20 mL by TRUS, a maximum flow rate of less than 15 mL/sec, and applying a lower threshold to the symptom severity (Garraway et al., 1993; Guess et al., 1993; Tsang and Garraway, 1993). By this definition, the prevalence of BPH increased at baseline from 14% in men in their 40s to 43% in men in their 60s, and about one-half of men reported interference with activities of daily living caused by LUTS and BPH. One-year and 3-year follow-up data have been reported (Lee et al., 1996). **From baseline to 3 years, the proportion of men with moderate symptoms increased from 34% to 45%, and significant increases in symptom level occurred for 8 of 12 symptoms queried and for the AUASI (increase from 6.37 to 7.88 from baseline to year 3, $P<0.0001$)** (Lee et al., 1996)**. Parallel to symptom frequency and severity, bothersomeness of symptoms increased over time (Fig. 144.21), and the proportion of men reporting interference with two or more activities increased from 26% to 41%, with three or more activities from 18% to 27%, and with four or more activities from 15% to 18%. This study clearly demonstrated LUTS and BPH being a progressive disease, albeit with a very flat slope of progression.**

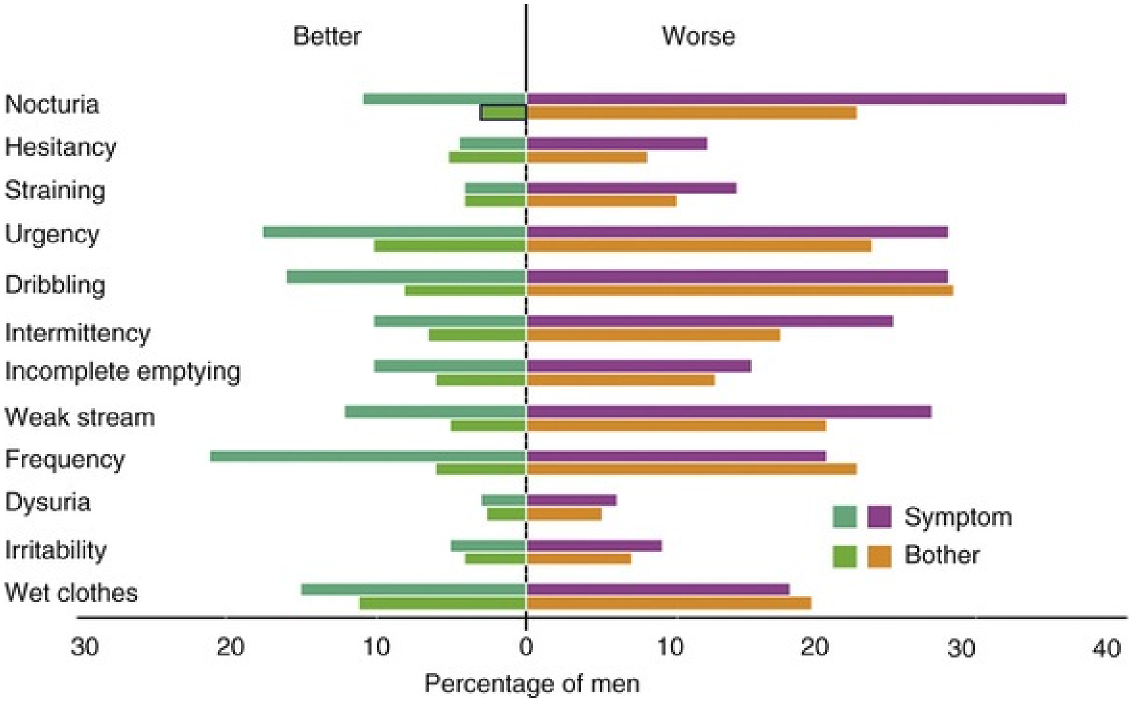

FIG. 144.21 Changes in urinary symptoms and bothersomeness status between baseline and 3 years in a Scottish population-based study. (From Lee AJ, Russell EB, Garraway WM, Prescott RJ. Three-year follow-up of a community-based cohort of men with untreated benign prostatic hyperplasia. *Eur Urol* 30[1]:11–17, 1996.)

The most informative natural history study to date is the Olmsted County Study of Urinary Symptoms and Health Status among Men, which has given us much information about prevalence and severity of urinary symptoms, bother, worry and embarrassment, quality of life caused by symptoms, and the relationship between symptoms and other parameters such as flow rates, prostate volume, and PSA (Girman et al., 1994, 1995; Guess et al., 1995; Jacobsen et al., 2003; Oesterling et al., 1993; Rule et al., 2005; Sarma et al., 2003).

With continued follow-up of this cohort, data have emerged regarding the longitudinal changes in symptoms and flow rate over time in this population-based study. Of 904 men reporting none to mild symptoms (AUASI 0 to 7 points) at baseline, 118 reported moderate to severe symptoms (AUASI >7 points) at 18 months, and 196 at 42 months of follow-up (Girman et al., 1995). However, 47 men who had developed moderate to severe symptoms at 18 months had none to mild symptoms at 42 months. At 42 months of follow-up, an average increase in the IPSS of 0.18 points (95% CI, 0.13 to 0.24) per year of follow-up was recorded. **The average annual symptom score slope and**

variability in slope increased with patient age at baseline from a mean of 0.05 +/– 1.06 (standard deviation) per year among men in the 40s to 0.44 +/– 1.35 per year for men in the 60s, and decreased to 0.14 +/– 1.42 per year for men in the 70s (Jacobsen et al., 1996)**. More recently, 92-month data showed an annual change of 0.34 points/year, with 31% of all men reporting at least a 3-point increase. The greatest annualized increase was observed in men in their 60s with 0.6 points/year** (Rhodes et al., 2000).

The Boston Area Community Health Survey enrolled 5502 participants 30 to 79 years of age with black, Hispanic, or white race/ethnicity (Piccolo et al., 2014). At 5-year follow-up interviews in 4144 participants, symptom progression, defined as an increase in AUASI by greater than 3 points, was reported by 21% to 33% of participants, and regression (decrease ≥3) was reported by 30% to 44% of participants, most commonly women and Hispanics. Age and higher BMI were associated with progression ($P<0.01$), but not regression (Maserejian et al., 2014) (Table 144.15).

TABLE 144.15

Change in LUTS Severity Classification: Age Adjusted Percentage of Men and Women With LUTS Severity at Follow-up by LUTS Severity at Baseline

BASELINE (PREVALENCE)	FOLLOW-UP IN MEN				BASELINE (PREVALENCE)	FOL
	NONE	MILD	MODERATE	SEVERE		NON
None (18.1)	26.8	69.9	2.8	0.5	None (13.7)	38.9
Mild (62.7)	12.2	77.0	10.3	0.5	Mild (67.4)	11.8
Moderate (18.4)	7.0	41.3	47.5	4.2	Moderate (17.0)	4.4
Severe (0.8)	0.8	1.0	36.7	61.5	Severe (1.9)	0

From Maserejian NN, Chen S, Chiu GR, et al. Treatment status and progression or regression of lower urinary tract symptoms among adults in a general population sample. *J Urol* 191(1):107–113, 2014.

Peak flow rate measurements in a subset of about 500 men from the Olmsted County Study showed a median peak urinary flow rate slope decrease of –2.1% per year (25th percentile –4.0, 75th percentile –0.6). Peak urinary flow rate declined more rapidly with decreasing baseline rate, and increasing baseline age, prostate volume and symptom severity (all P = 0.001). When the variables were simultaneously adjusted for each other, a rapid decline (negative slope 4.5% or greater per year) was more likely in

men 70 years of age or older and those with a rate less than 10 mL/sec at baseline compared with those 40 to 49 years of age and those with a rate of 15 mL/sec or greater, respectively. Prostate volume and symptom severity were not statistically significant predictors of a rapid decline in peak urinary flow rate when variables were considered simultaneously (Roberts et al., 2000).

Based on TRUS, the growth of the prostate in these men 40 to 79 years of age was estimated to be about 0.6 mL per year or 6 mL per decade of life. However, prostate growth followed an exponential growth pattern, with a slope estimate of 0.4 mL/year for men 40 to 59 years of age at baseline and of 1.2 mL/year for those 60 to 79 years of age at baseline (Rhodes et al., 1995, 1999). An updated analysis revealed a median growth rate of about 1.9%/year independent of age and symptoms. However, a higher baseline serum PSA and larger prostate volume predicted greater annualized volume increases.

Complications of Benign Prostatic Hyperplasia

Many of the complications of progressive BPH are rare, and much of the knowledge comes from studies of men presenting with such complications for treatment, that is, cases, rather than observing cohorts of men for the development of complications.

Mortality

Between 1950 and 1954, 17 of 24 countries reported mortality rates of greater than 10 per 100,000, and between 1985 and 1989 data were available for 61 countries, only one reporting a greater than 10/100,000 mortality rate (Boyle et al., 1996). **If the mortality rates from 1950 were applied to 1990, 13,681 fewer deaths occurred in the United States alone than expected, a major but unheralded health care achievement.**

Bladder Stones

In a large autopsy study, the prevalence of bladder stones was 8 times higher in men with a histologic diagnosis of BPH (3.4%) compared with controls (0.4%), but no increased incidence of ureteral or kidney stones was found (Grosse, 1990). In a study comparing watchful waiting and TURP in men with moderate symptoms, only 1 of 276 patients assigned to watchful waiting developed a bladder stone at 3-year follow-up (Wasson et al., 1995). The self-reported rate of a bladder stone in a cross-sectional study in 2002 Spanish men was 0.7% (Hunter et al., 1996).

In clinical practice, the risk for bladder stone development is small, and screening is only indicated if clinical circumstances warrant it (e.g., hematuria, stuttering of urination).

Bladder Decompensation

When endoscopically evaluating the bladder in men with BPH, urologists search for a progression from normal mucosa to advancing trabeculation,

development of cellules, and diverticula, with ultimate detrusor muscle failure in mind. However, when the process starts, it is unclear whether it really is related to BPH and obstruction and when an intervention is necessary to prevent decompensation with resultant inability to void.

Biopsies from trabeculated, obstructed bladders show dense connective tissue deposition, a finding similar to that seen in experimentally obstructed animals (Chapple et al., 1991; Gosling and Dixon, 1980; Levin et al., 1990, 2000). However, bladder fibrosis is seen in both sexes with advancing age and may be a normal consequence of aging (Lepor et al., 1992b).

The critical question is whether or not delayed intervention might lead to progressive irreversible loss of bladder function and misses a window for cure. There is no direct evidence for this from longitudinal population or clinic patient studies. However, in the VA Cooperative study comparing watchful waiting with TURP, the patients who crossed over from the conservative arm to TURP later in the trial did not have as significant an improvement in symptoms and flow rate compared with those who underwent TURP at the beginning after randomization (Flanigan et al., 1998).

The topic continues to be of interest, and a recent literature review emphasized the absence of high-quality data and the importance of the “design of longitudinal, prospective randomised studies evaluating early pharmacological/surgical treatments versus deferred interventions to better identify the clinical profile of patients who could best benefit from early intervention and the ideal type and time of it” (Presicce et al., 2018).

Urinary Incontinence

Incontinence is one of the most feared complications from surgical intervention for BPH. Although it may be the result of BPH secondary to overdistension of the bladder (overflow incontinence) or to detrusor instability estimated to affect up to one-half or more of all obstructed patients (urge incontinence) (McConnell, 1994), it also is associated with aging, and in a community study an incidence of incontinence of 24% and 49%, respectively, in men and women older than 50 years of age was reported (Roberts et al., 1998). In the VA Cooperative study, a 4% incidence of incontinence in both the surgical and conservative treatment arms was reported (Wasson et al., 1995). The self-reported rate of incontinence in a cross-sectional study in 2002 Spanish men was 6.1% (Hunter et al., 1996). In the MTOPS, the rate of socially unacceptable incontinence was 0.3/100 patient-year (McConnell et al., 2003).

Urinary Tract Infections

In older surgical series, UTIs constitute the main indication for surgical intervention in about 12% (Holtgrewe et al., 1989; Mebust et al., 1989). **Although one might intuitively assume that increased amounts of residual urine would predispose to the development of UTI, clear evidence is lacking.** Hunter quoted a rate of 5.2% self-reported episodes of UTI in a cross-sectional survey of 2002 men in Madrid, Spain (Hunter et al., 1996). The best data to date come from the MTOPS study, where the incidence of UTIs in the placebo-treated patients was only 0.1/100 patient-years (McConnell et al., 2003).

Upper Urinary Tract Deterioration and Azotemia

The Agency for Health Care Policy and Research BPH guidelines reported a mean of 13.6% (range from 0.3% to 30%) of patients presenting for TURP with evidence of renal failure based on predominantly older studies (McConnell et al., 1994). Patients in renal failure have an increased risk for complications after TURP compared with those with normal renal function (25% vs. 17%) (Holtgrewe et al., 1989; Mebust et al., 1989), and the mortality rate increases up to sixfold (Holtgrewe and Valk, 1962; Melchior et al., 1974a, 1974b). In the large database of patients who had upper tract imaging before surgery, 7.6% of 6102 patients in 25 series had evidence of hydronephrosis, of whom one-third had renal insufficiency (McConnell et al., 1994).

The term *silent obstruction* or *silent prostatism* has been used to describe the constellation of asymptomatic patients who eventually develop renal failure resulting from bladder outlet obstruction, a case both rare and important (Mukamel et al., 1979). In the VA Cooperative study, only 3 of 280 surgically treated patients and 1 of 276 patients in the watchful waiting arm developed renal azotemia, defined as a doubling of serum creatinine from baseline (Wasson et al., 1995). In none of the cohort or population-based studies have cases of renal failure been reported clearly attributable to BPH. However, the self-reported rate of an episode of renal failure in a cross-sectional study in 2002 Spanish men was 2.4% (Hunter et al., 1996).

In the MTOPS, there was no single case of renal insufficiency caused by BPH in more than 3000 men followed for over 4 years (McConnell et al., 2003). One has to be, however, careful not to overinterpret these findings. Participants in the MTOPS were screened at baseline, and one might argue that some at higher risk for developing renal failure were excluded from participation.

Hematuria

It has always been recognized that patients with BPH might develop gross hematuria and form clots with no other cause being identifiable. Recent evidence suggests that in patients predisposed to hematuria, microvessel density is higher compared with controls. Some renewed interest in the issue of BPH-related hematuria stems from the observation that finasteride appears to be a reasonable first-line therapy apparently influencing the expression of VEGF (DiPaola et al., 2001). The self-reported rate of hematuria in a cross-sectional study in 2002 Spanish men was 2.5% (Hunter et al., 1996). Precise population estimates and incidence rates are not available, and the clinical management is dictated by the circumstances.

Acute Urinary Retention

AUR is for several reasons one of the most significant complications or long-term outcomes resulting from BPH. It has in the past represented an immediate indication for surgery. Between 25% and 30% of men who underwent TURP had AUR as their main indication in older series (Holtgrewe et al., 1989; Mebust et al., 1989)**, and today most patients failing to void after an attempt of catheter removal still undergo surgery. For this reason alone, AUR is both an important and feared event from an economical perspective and from the viewpoint of the patient.** For the patient, it presents itself by the inability to urinate with increasing pain, eventually a visit to the emergency room, catheterization, follow-up visits to physicians, an attempt at catheter removal, and either recovery of spontaneous voiding or surgery, both a painful and time-consuming process. In older literature, the risk for recurrent AUR was cited as being 56% to 64% within 1 week of the first episode and 76% to 83% in men with diagnosed BPH (Breum et al., 1982; Hastie et al., 1990; Klarskov et al., 1987).

The etiology of AUR is poorly understood, and obstructive, myogenic, and neurogenic causes all may play a role (Kaplan et al., 2008)**. Prostate infection, bladder overdistension** (Powell et al., 1980)**, excessive fluid intake,**

alcohol consumption, sexual activity, debility, and bed rest have all been mentioned (Stimson and Fihn, 1990)**. Prostatic infarction has been suggested as being an underlying event causing AUR** (Graversen et al., 1989). Spiro et al. (1974) found evidence for infarction in 85% of prostates removed for AUR versus 3% in prostates of men having surgery for symptoms only. In contrast, there was no evidence of infarction in six prostatectomy specimens removed from men who had surgery for AUR (Jacobsen et al., 1997). Anjum found fundamentally similar rates of infarction in 35 men each in AUR versus no AUR (1.9% vs. 3.0%) (Anjum et al., 1998).

From a clinical and prognostic point of view, spontaneous AUR should be separated from precipitated AUR, although this is by no means consistently done in the literature. Precipitated AUR refers to the inability to urinate after a triggering event such as non–prostate-related surgery; catheterization; anesthesia; ingestion of medications with α-sympathomimetic or anticholinergic effects or antihistamines; or others. All other AUR episodes are classified as spontaneous (Roehrborn et al., 2000b). The importance of differentiating the two types of AUR becomes clear when evaluating the ultimate outcomes of patients. After spontaneous AUR, 15% of patients had another episode of spontaneous AUR, and a total of 75% underwent surgery, and after precipitated AUR, only 9% had an episode of spontaneous AUR, and 26% underwent spontaneous surgery (Roehrborn et al., 2000a).

Descriptive Epidemiology (*Table 144.16*)

Older estimates of occurrence of AUR range from 4 to 15 to as high as 130 per 1000 person-years (calculated by Jacobsen et al., 1997) based on studies (by Ball et al., 1981; Birkhoff et al., 1976; Craigen et al., 1969), which leads to 10-year cumulative incidence rates ranging from 4% to 73%. The self-reported rate of AUR in a cross-sectional study in 2002 Spanish men was 5.1% (Hunter et al., 1996).

TABLE 144.16

More recent data from carefully controlled studies in better defined populations shed additional light on the incidence rates in community-dwelling men and clinical BPH populations. AUR occurred in the VA Cooperative study over 3 years in 1 man after TURP and in 8 of 276 men in the watchful waiting arm for an incidence rate of 9.6/1000 person-years (Wasson et al., 1995). Barry et al. (1997) reported outcomes of 500 men diagnosed by urologists with BPH, who were candidates for prostatectomy by established criteria but elected to be followed conservatively. In 1574 person-years, 40 episodes of AUR occurred at a constant rate throughout the 4 years of follow-up for an incidence rate of 25/1000 person-years.

During 15,851 person-years of follow-up in the Physicians Health Study, 82 men reported an episode of AUR for an incidence rate of 4.5/1000 person-years

(95% CI, 3.1 to 6.2) (Meigs et al., 1999). Of the 2115 men 40-79 years of age in the Olmsted County Study, 57 had a first episode of AUR during 8344 person-years of follow-p (incidence 6.8/1000 person-years, 95% CI, 5.2 to 8.9) (Jacobsen et al., 1997).

The first excellent data from men diagnosed with BPH stem from the PLESS (McConnell et al., 1998)**. In the PLESS, 1376 placebo-treated men with enlarged prostates and moderate symptoms had complete follow-up over 4 years, of which 99 experienced an episode of AUR for a calculated incidence rate of 1.8/100 person-years. Boyle** (1998) **meta-analyzed the placebo treatment groups from three 2-year studies with a similar patient population. Of 2109 patients, 57 experienced AUR over the 2 years with a constant hazard for an incidence rate of 14/1,000 person-years. In the MTOPS placebo group, the incidence rate was 0.6/100 patient-years for a cumulative incidence of 2%.**

Analytical Epidemiology

Age.

Several well-controlled studies provided considerable insights into the risk factors for AUR. Perhaps the most significant of these risk factors is age. Studies from European countries and the United States demonstrate a nearly linear increase in the age-specific incidence of AUR for men ranging from 40 to over 80 years of age (Cathcart et al., 2006; Jacobsen et al., 1997; Meigs et al., 1999; Verhamme et al., 2005) (Fig. 144.22).

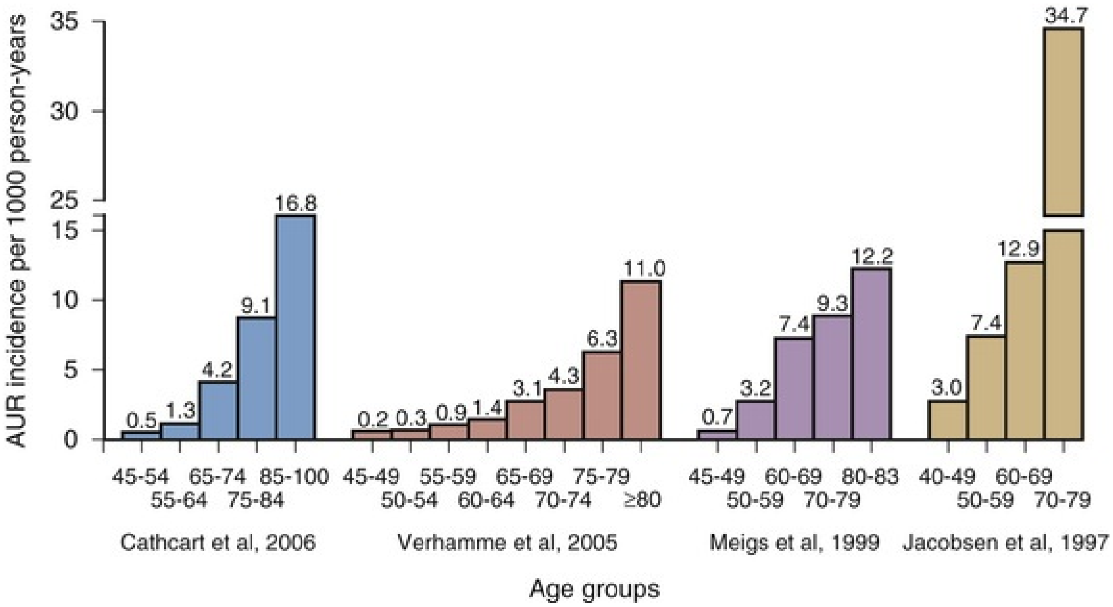

FIG. 144.22 Increase in incidence of acute urinary retention *(AUR)* with age in four large studies. (From Kaplan SA, Wein AJ, Staskin DR, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. *J Urol* 180[1]:47–54, 2008.)

LUTS.

Increased symptom severity was associated with increased risk for AUR in several large population-based or cohort studies (Table 144.17). In the Physician's Health Study in men with mild symptoms, the incidence of AUR increased from 0.4/1000 person-years for those 45 to 49 years of age to 7.9/1000 person-years for those 70 to 83 years of age. In men with a symptom score of 8 to 35, rates increased from 3.3/1000 person-years for those 45 to 49 years of age to 11.3/1000 person-years for those 70 to 83 years of age. Men with a clinical diagnosis of BPH and a symptom score of 8 or greater had the highest rates (age-adjusted incidence 13.7/1000 person-years). All seven LUTS comprising the American Urological Association (AUA) symptom index individually predicted AUR. The sensation of incomplete bladder emptying, having to void again after less than 2 hours, and a weak urinary stream were the best independent symptom predictors. Use of medications with adrenergic or anticholinergic side effects also predicted AUR (Meigs et al., 1999).

[a] Total of 82 AUR episodes in 6100 men with a crude incidence of 5.2/1000 patient-years (95% CI 4.1–6.4) in 15,851 patient-years of follow-up.

[b] Total of 57 AUR episodes in 2115 men with an overall incidence of 6.8/1000 patient-years (95% CI 5.2–8.9) in 8344 patient-years of follow-up.

AUASI, American Urological Association Symptom Index; *AUR,* acute urinary retention; *CI,* confidence interval.

From Kaplan SA, Wein AJ, Staskin DR, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. *J Urol* 180(1):47–54, 2008.

The Olmsted County Study analyses focused on age, symptom severity, maximum flow rate, and prostate volume (Jacobsen et al., 1997). **Incidence rates per 1000 person-years increased from 2.6 to 9.3 for men in their 40s to 70s if they had mild symptoms and from 3.0 to 34.7 if they had more than mild symptoms.**

Urodynamic Parameters.

The relative risk increased for older men, men with moderate to severe symptoms (3.2×), those with a flow rate less than 12 mL/sec (3.9×), and those with a prostate volume greater than 30 mL by TRUS (3.0×), all compared with a baseline risk for 1.0× for the corresponding groups (Fig. 144.23). The highest relative risk by proportional hazard models exists for men

60 to 69 years of age with more than mild symptoms and a flow rate less than 12 mL/sec (10.3×), and for men 70 to 79 years of age, except if they had mild symptoms and a flow rate greater than 12 mL/sec. All other stratification of men older than 70 years of age had a RR ranging from 12.9× to 14.8× (all compared with men 40 to 49 years of age with mild symptoms and a flow rate greater than 12 mL/sec for which the base risk is 1.0×).

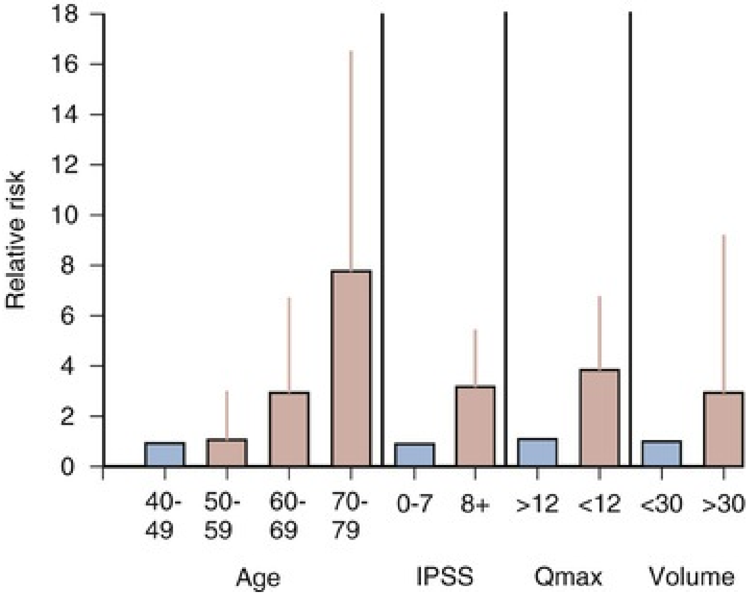

FIG. 144.23 Relative risk of acute urinary retention in Olmsted County Study of Urinary Symptoms and Health Status Among Men by age, symptom severity, peak flow rate, and prostate volume. The shaded column represents the baseline and a relative risk of 1.0; the vertical line represents the 95% confidence interval. *IPSS,* International Prostate Symptom Score. (Data from Jacobsen SJ, Jacobson DJ, Girman CJ, et al. Natural history of prostatism: risk factors for acute urinary retention. *J Urol* 158[2]:481–487, 1997.)

Prostate Volume and Serum PSA.

Although age in community-dwelling men is an important risk factor, in a BPH trial population of men who already are diagnosed with BPH, other factors can be analyzed. In the placebo groups of three 2-year studies (Marberger et al., 2000) and a 4-year study (PLESS) prostate volume, serum PSA, and symptom severity all were predictors of AUR episodes (Kaplan et al., 2000; McConnell et al., 1998; Roehrborn et al., 2000a).

The incidence increased from 5.6% to 7.7% in men with a serum PSA less

than 1.4 ng/mL from mild to severe symptoms, and from 7.8% to 10.2% for those with a serum PSA greater than 1.4 ng/mL over 4 years in the PLESS (Kaplan et al., 2000). In the 2-year studies, the rate of AUR was eightfold higher in those with a serum PSA greater than 1.4 ng/mL (0.4 vs. 3.9%) and threefold higher if the prostate volume was greater than 40 mL (1.6 vs. 4.2%) (Marberger et al., 2000; Roehrborn, 2001). **A detailed analysis showed a near linear increase in risk for AUR with increasing thresholds of serum PSA (**Fig. 144.24**) in the PLESS, an observation that applies to both spontaneous and precipitated AUR** (Roehrborn et al., 1999b)**. The risk for both types of AUR increases with increasing serum PSA and prostate volume stratified by tertiles (Fig. 144.25).** Similar observations were made in the MTOPS, where the risk for AUR increased with increasing prostate volume and increasing baseline serum PSA (Fig. 144.26), **and in the 2-year phase III studies comparing dutasteride with placebo** (Roehrborn et al., 2002)**. An analysis of more than 100 possible outcome predictors alone or in combination revealed a combination of serum PSA, urinating more than every 2 hours, symptom problem index, maximum urinary flow rate, and hesitancy as being only slightly superior to PSA alone in predicting AUR episodes** (Roehrborn et al., 2001).

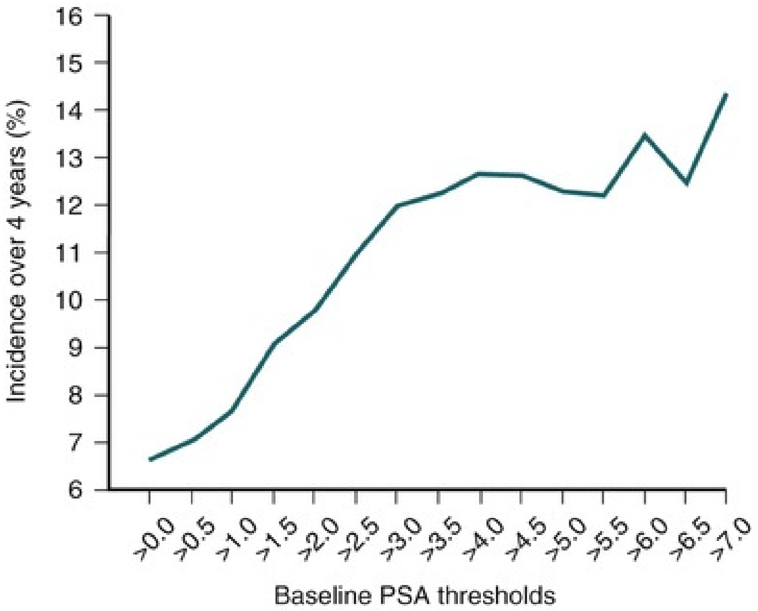

FIG. 144.24 Incidence of spontaneous or precipitated acute urinary retention in the Proscar Long-Term Efficacy and Safety Study over 4 years stratified by increasing thresholds of serum prostate-specific antigen *(PSA)* at baseline. (From Roehrborn CG, McConnell JD, Lieber M, et al. Serum

prostate-specific antigen concentration is a powerful predictor of acute urinary retention and need for surgery in men with clinical benign prostatic hyperplasia. PLESS Study Group. *Urology* 53[3]:473–480, 1999.)

Surgery for Benign Prostatic Hyperplasia

Both surgery and AUR represent distinct endpoints in the disease progression of BPH. There are, however, distinct differences. AUR is an outcome mandating management, and surgery is one of the commonly employed management styles. AUR is probably one of the clearer indications for surgery, leaving the treating physician little choice in a patient who failed a trial without catheter (TWOC). However, most patients undergo surgery for symptoms, not for AUR (Holtgrewe et al., 1989)**. Depending on local practice pattern, AUR accounts for 5% to over 30% of the indications for surgery. AUR can be compared with a bone fracture. It is impossible for the physician in his or her interaction with the patient to increase or decrease the probability for this outcome to occur. Furthermore, once it has occurred, no interaction or consultation can undo it. In contrast, it is easy to see how patients can be influenced in their decision to undergo surgery by the consultation with the physician. The interaction style, the quoted probabilities of beneficial and harmful outcomes to occur, and many other factors cause considerable variability in the incidence rates of prostate-related surgery, an observation that caused the AHCPR to develop guidelines for the treatment of BPH** (Wennberg et al., 1988). This situation is similar to myocardial infarction (MI) and coronary artery bypass grafting (CABG). The analytical epidemiology of MI is well understood, and risk factors are characterized. Not all MIs result in CABG, and in fact CABG is frequently performed for other indications than a recent MI. Consequently, there is abundant literature focusing on the geographic variation in the usage of CABG. **From this brief discussion, it becomes clear that surgery for BPH is a softer endpoint from an epidemiologic point of view than AUR, and data on rates of prostatectomy need to be interpreted in light of variation in its use, from provider to provider, region to region, health care plan to health care plan, and over time.**

Of all prostate surgeries, TURP and laser ablation of the prostate are still clearly the most common procedures and the best studied ones. Cross-sectional descriptive data on incidence rates are available from the Medicare database. Although in 1962 TURP constituted over 50% of all major surgeries performed by American urologists, this number dropped to 38% by 1986 (Holtgrewe et al., 1989; Mebust et al., 1989). Although the number of TURPs performed on

Medicare patients declined from an all-time peak of 258,000 in 1987 to 168,000 in 1993 (a reduction of 34%), it remains second only to cataract surgery on the list of Medicare's most costly surgical procedures. A 20% sample of Medicare beneficiaries was examined to further specify rates of TURP in the United States. In 1990, the rates of TURP (including all indications) were approximately 25, 19, and 13 per 1000 for men older than 75, 70 to 74, and 65 to 69 years of age, respectively. The 30-day mortality rate after TURP for the treatment of BPH decreased from 1.20% in 1984 to 0.77% in 1990 (Lu-Yao et al., 1994). **Compared with 1984 to 1990, age-adjusted rates of TURP for BPH during 1991 to 1997 declined further by approximately 50% for white men (14.6 to 6.72/1000) and 40% for black men (11.8 to 6.58/1000)** (Wasson et al., 2000). Medicare databases are only relevant to those men older than 65 years of age who are enrolled in Medicare, and therefore are less interesting from a longitudinal epidemiologic point of view.

Older series on the natural history of BPH such as the one reported by Craigen et al. projected somewhat unrealistic estimates of 35% incidence of prostatectomy at 1 year and 45% at 7 years (Craigen et al., 1969). Diokno reported an annual incidence rate of 2.6% and 3.3% for years 1 and 2 in his cohort of men followed longitudinally (Diokno et al., 1992). Frequency, hesitancy, straining, and an interrupted stream were all associated with increased risk.

The first study of substantial quality reporting on incidence rates and risk factors of prostate surgery was the Baltimore Longitudinal Study of Aging (BLSA) (Arrighi et al., 1990, 1991; Guess et al., 1990). More than 1000 men were followed for 30 years with yearly symptom assessments, questionnaires, and examinations. **Age, incomplete emptying, change in size, and force of stream were all independently associated with the risk for prostate surgery, as was a reportedly enlarged prostate by DRE.** Of 464 men without risk factors, only 3% required surgery during follow-up. For men with one risk factor, the cumulative incidence was 9%, with two risk factors 16%, and with three risk factors even 37%. In a similar study, namely the VA Normative Aging Study, nocturia and hesitancy emerged as independent predictors of surgery in 1868 men 49 to 68 years of age followed for more than 20 years (Hindley et al., 2001). Age and five LUTS (dysuria, incontinence, trouble initiating flow, nocturia, and slow stream) were associated with the risk for surgery in 16,219 men older than 40 years of age enrolled in the Kaiser Permanente Health Plan in California, of whom 1027 men underwent prostatectomy over 12 years of follow-up (Sidney et al., 1991a,b).

In the VA Cooperative trial comparing surgery with watchful waiting, 65 of 276 (24%) patients assigned to watchful waiting crossed over to surgery within 3 years of follow-up, of which 20 met predefined endpoints (azotemia, high residuals, incontinence, or high symptom scores). High baseline bother score was a strong predictor of requiring surgery (Wasson et al., 1995).

The probability of undergoing surgery over 4 years increased from 10% in men diagnosed with BPH who had mild symptoms to 24% in those with moderate symptoms and 39% in those with severe symptoms at baseline, as reported in a natural history and observation study (Barry et al., 1997).

The Olmsted County Study and the placebo-treated patients from the PLESS provide additional insight into the risk factors for undergoing prostate surgery in either community-dwelling men or men enrolled in a BPH treatment trial.

In the Olmsted County study during more than 10,000 person-years of follow-up, 167 men were treated, yielding an overall incidence of 16.0/1000 person-years. There was a strong age-related increase in risk for any treatment from 3.3/1000 person-years for men 40 to 49 years of age to more than 30/1000 person-years for those 70 years of age or older. Men with moderate to severe symptoms, depressed peak urinary flow rates (< 12 mL/sec), enlarged prostate (>30 mL), or elevated serum PSA (≥1.4 ng/mL) had about four times the risk for BPH treatment than those who did not. After adjustment for all measures simultaneously, an enlarged prostate (HR 2.3, 95% CI, 1.1 to 4.7), depressed peak flow rate (HR 2.7, 95% CI, 1.4 to 5.3), and moderate to severe symptoms (HR 5.3, 95% CI, 2.5 to 11.1) at baseline each independently predicted subsequent treatment. Overall nearly 1 in 4 men received treatment in the eighth decade of life. **These data suggest that men with moderate to severe LUTS, impaired flow rate, or enlarged prostate are more likely to undergo treatment, with increases in risk for similar magnitude to those associated with adverse outcomes such as AUR** (Jacobsen et al., 1999).

Over 1500 patients with moderate LUTS and enlarged prostate glands were followed in the PLESS on placebo for 4 years. Of these, 10% or 2.5% per year underwent surgery for BPH (McConnell et al., 1998). Although the hazard of undergoing surgery was linear (i.e., it remained constant throughout the duration of the study), it was different when patients were stratified by either prostate volume or serum PSA in tertiles at the beginning of the study (Fig. 144.27). **Similar to the incidence of AUR, the rates of surgery increased from 6.2% to 14.6% for patients in the lowest to the highest PSA tertile, and from 6.7%**

to 14.0% from the lowest to the highest prostate volume tertile. In the MTOPS, the incidence of invasive therapy for BPH in the placebo group increased equally nearly linearly when stratifying by baseline serum PSA or prostate volume (Fig. 144.28) (McConnell et al., 2003).

Serum prostate-specific antigen concentration is a powerful predictor of acute urinary retention and need for surgery in men with clinical benign prostatic hyperplasia. PLESS Study Group. *Urology* 53[3]:473–480, 1999.)

Key Points

- The autopsy prevalence of BPH increases linearly starting at 40 years of age and is remarkably similar across cultures and ethnicities.
- Cross-sectional studies suggest increases in LUTS severity, frequency, bother, and quality-of-life impairment with age that are fundamentally similar in all societies studied.
- Analytical studies have failed to reveal significant risk factors for the development of BPH and LUTS.
- The natural history of BPH in individual patients is highly variable measured primarily by prostate volume growth
- Interindividual variability is also noted in secondary physiologic measures such as urinary flow and residual urine, and the development of complication and the risk for urinary retention and the need for surgery
- There are certain baseline factors allowing an assessment of risk for volume

growth, progression and risk for complications.

Evaluation and Nonsurgical Management of Benign Prostatic Hyperplasia

---

Paolo Capogrosso MD, Andrea Salonia MD, PhD, Francesco Montorsi MD, FRCS (Hon)

The term **benign prostatic hyperplasia (BPH)** has been historically used to define a disease characterized by symptoms of urinary dysfunction as a consequence of an obstacle to micturition caused by an enlarged prostate. During recent decades, the acronym **LUTS (i.e., lower urinary tract symptoms)** has been introduced as an umbrella term to define a complex of symptoms involving dysfunction of both the storage phase and the voiding phase of micturition, and BPH has been referred to a histologic diagnosis characterized by the proliferation of smooth muscle and epithelial cells within the prostatic transition zone (Abrams 1994; Abrams et al., 1982; Chapple et al., 2008).

LUTS are considered as a clinical manifestation with a multifactorial pathophysiology arising from different conditions, including bladder outlet obstruction (BOO) possibly caused by benign prostatic obstruction (BPO), associated with benign prostatic enlargement (BPE), and potentially resulting from the histologic condition of BPH (Abrams et al., 2002). However, LUTS may also be the expression of nonprostatic conditions, such as bladder dysfunction (e.g., detrusor overactivity [DO] or detrusor underactivity [DUA]), urethral strictures, or urinary tract infections (UTIs) (Chapple et al., 2008). In addition, nonurologic conditions involving hormonal, metabolic, and cardiovascular processes (Chapple et al., 2008; Gacci et al., 2016a) and neurologic diseases (Panicker et al., 2015) can be responsible for LUTS as a whole.

It is clear that patients bothered by LUTS and seeking first medical help cannot be regarded as affected only by BOO caused by BPH until a more comprehensive assessment of their condition has been undertaken. Therefore, as currently outlined by a number of international clinical guidelines (Gratzke et al., 2015; McVary et al., 2011), a physician should follow a diagnostic algorithm aimed to assess LUTS severity and identify the pathogenesis, which would further drive therapeutic management.

In this chapter, we discuss patient workup in men seeking first medical help because of LUTS, focusing on the clinical management of those bothered by LUTS caused by BOO associated with BPE resulting from BPH.

Diagnostic Evaluation

LUTS are a complex of symptoms bothering up to 51.3% of men (Irwin et al., 2006) with a detrimental impact on health-related quality of life (QoL) (Kupelian et al., 2006), and a consequent relevant social and economic burden. **The proper diagnostic assessment of men complaining of LUTS represents a major issue in the everyday clinical practice of both general physicians and urologists.**

The diagnostic workup of every patient with LUTS should aim at evaluating the severity of symptoms and their impact on a patient's QoL, and the proper assessment of the underlying conditions, which is essential for correct therapeutic management.

A basic diagnostic evaluation, including medical history, physical examination, and urinalysis, is often crucial to exclude most—if not all—nonprostatic causes of LUTS. Additional diagnostic tests could be further required to better clarify the diagnosis, improve disease severity estimation, and predict the response to treatment. The American Urological Association (AUA) BPH guidelines were last updated in 2010 (McVary et al., 2011). The full version is available at: http://www.auanet.org/guidelines/benign-prostatic-hyperplasia-(2010-reviewed-and-validity-confirmed-2014); the European Association of Urology (EAU) has more recently updated its guidelines regarding the clinical evaluation and treatment of nonneurogenic male LUTS (Gratzke et al., 2015; Oelke et al., 2013). The full version is available at: https://uroweb.org/wp-content/uploads/EAU-Guidelines-Management-of-no n-neurogenic-male-LUTS-2016.pdf.

Medical History

Both internationally published guidelines and expert consensus panels emphasize the importance of a comprehensive medical history as a first step in the evaluation of patients with LUTS (Gratzke et al., 2015; McVary et al., 2011). **The main goal of the baseline interview of any patient is to identify potential causes of LUTS so as to further address the diagnostic and therapeutic decision-making process with a more patient-tailored approach.**

Patients should be comprehensively evaluated in terms of comorbidities, with a specific focus on those medical conditions potentially associated with LUTS, including diabetes (either diabetes mellitus or diabetes insipidus), renal diseases, heart failure, sleep apnea, and neurologic diseases (e.g., Parkinson's disease, multiple sclerosis, cerebrovascular disease, spinal cord injury, or prolapsed intervertebral disc impinging on the spinal cord) (Gratzke et al., 2015). A history of conditions affecting the lower urinary tract and the occurrence of gross hematuria should be investigated as well, along with the history of any previous surgical intervention involving the prostate, bladder, or urethra. It is recommended to assess any medication potentially worsening storage symptoms, such as loop diuretics and β-blockers (Lewandowski et al., 2013; Ruby et al., 2010), and also anticholinergic drugs, which may significantly impair bladder contractility.

In addition, emotional and psychological factors and lifestyle habits should be assessed: the association between food and fluid intake and LUTS severity has recently been reviewed, showing a negative impact of increased fluid and caffeine intake on storage symptoms (Bradley et al., 2017). Similarly, a bidirectional association between LUTS and emotional distress has been reported (Coyne et al., 2009).

As a final task, physicians should reassure the patient regarding the lack of an association between LUTS and prostate cancer (PCa) risk (Gratzke et al., 2015).

Symptom Assessment

LUTS can be ascribed to the macrocategories of voiding and storage phase impairment: the former includes weak urinary stream, sensation of incomplete urination, hesitancy, straining, prolonged micturition, and dribbling; the latter includes frequency, urgency, urge incontinence, and nocturia (Abrams 1994; Chapple et al., 2008). Voiding symptoms in men are frequently related to BOO, although they cannot always be ascribed to BPE/BPH (Abrams et al., 2002; Chapple et al., 2008). Likewise, storage symptoms, which have been recently largely encompassed by the term *overactive bladder (OAB) syndrome*, also can be associated with an obstacle to micturition eventually caused by BPE/BPH (Chapple et al., 2008; Drake 2014).

The quantification of symptom severity and the assessment of how a given level of symptoms may affect each man's QoL (degree of associated bothersome) provides valuable information in terms of the severity of disease, response to therapy, and risk for disease progression.

Patient-reported outcomes, through the use of internationally validated questionnaires, are currently considered the gold standard to assess disease severity in the primary setting (Gratzke et al., 2015; McVary et al., 2011). Barry et al. (1992) developed and validated the American Urological Association Symptom Index (AUASI) for BPH. The AUASI includes seven questions investigating frequency, nocturia, weak urinary stream, hesitancy, intermittence, incomplete emptying, and urgency: a score of 0 to 5 points can be assigned to each question, producing a total symptom score ranging from 0 to 35. According to the final score, symptoms can be classified as mild (0 to 7), moderate (8 to 19), or severe (20 to 35). This seven-question set is internally consistent and reliable, correlates strongly with patients' global ratings of their urinary difficulties, and is sensitive to treatment response. In 1993, the World Health of Organization adapted the AUASI to create the International Prostate Symptom Score (IPSS), which is based on the original seven questions combined with one more question devoted to assessing the degree to which patients find their symptoms bothersome (bother score) (Cockett et al., 1994). **The IPSS is currently considered the international standard tool to investigate LUTS severity.**

Recently a further segregation of the IPSS into storage (three questions) and voiding (four questions) subscales was suggested to provide a more reliable measure of storage and voiding dysfunctions, although these subscales have not been validated yet.

Despite the accuracy of both the AUASI and the IPSS in assessing LUTS severity, these tools are not intended to be used for a clinical diagnosis of BOO (Gratzke et al., 2015; McVary et al., 2011). Indeed LUTS severity has been poorly correlated with the underlying pathophysiology (McVary et al., 2011; Gratzke et al., 2015). D'Silva et al. (2014) reviewed available evidence for the diagnostic accuracy of questionnaires widely used to diagnose BOO, using urodynamic multichannel studies as a reference standard. They reported a likelihood ratio 95% confidence interval (CI) of 1.1 to 2.0 for patients with an IPSS above 20 and 0.67 to 1.00 for patients with an IPSS below 20. Their findings confirmed the poor diagnostic accuracy of the IPSS as a single instrument to identify patients with BOO.

Beside the IPSS, other tools have been developed and validated to investigate LUTS severity and treatment outcomes. To this specific aim, an AUA committee developed the BPH Impact Index (BII), assessing the impact of BPH symptoms on patients' health and functioning (Barry et al., 1995). The BII is a four-question tool dealing with urinary symptoms concerning physical discomfort, concern for individual health, how bothersome symptoms are, and whether the symptoms are interfering with usual activities. The International Consultation on Incontinence Modular Questionnaire—male LUTS (ICIQ-MLUTS) was derived from the International Continence Society (ICS) male questionnaire, and allows evaluation of the degree of bother associated with a specific symptom, using a 0 to 10 linear analog scale (Abrams et al., 2006a). Similarly, the Danish Prostate Symptom Score (DAN-PSS) showed good correlation with LUTS severity, and is sensitive to symptom changes after therapy (Pannek et al., 1998). However, compared with the IPSS, the DAN-PSS does not correlate with obstruction (Pannek et al., 1998). In addition, given the high prevalence of storage symptoms affecting also the female counterpart (Irwin et al., 2006), specific tools—such as the Overactive Bladder Symptom Score (OABSS) (Homma et al., 2006) and the Overactive Bladder Questionnaire (OAB-q)—have been specifically developed to assess storage symptoms and their impact on QoL (Coyne et al., 2002). Both tools could be useful for a comprehensive estimation of the degree of symptom-associated bother for patients with a prevalent storage component.

Finally, evidence of a strong link between LUTS/BPH and sexual dysfunction (Rosen et al., 2003) supports the investigation of sexual issues, which may negatively affect a patient's QoL and deserve further attention (Gratzke et al., 2015).

Physical Examination

Physical examination is an important step in the basic workup of every patient complaining of LUTS, and should not be neglected (Gratzke et al., 2015; McVary et al., 2011). Physicians should accurately assess the male pelvis, mostly to identify disorders potentially associated with LUTS. To this aim, the suprapubic area must be inspected to exclude an overdistended, palpable, or percussable bladder. Moreover, the penis deserves to be carefully evaluated to exclude any stricture of the external meatus, potentially responsible for BOO, as well as the presence of a phimosis or of malignant lesions of the penile skin/foreskin. The ventral side of the penis should be palpated to search for palpable urethral masses as an indirect sign of strictures. Similarly, the presence of urethral discharges should be taken into consideration as a sign of urethritis. The scrotum and the testicles should always be examined to look for signs of orchiepididymitis. Moreover, the evaluation of testicular size along with other secondary male sex characteristics (e.g., body hair, pattern of hair loss) may be useful to detect a low testosterone level, which could be associated with central obesity and metabolic alterations suggestive of metabolic syndrome. Indeed, the association between metabolic alterations and BPE has been widely demonstrated (Gacci et al., 2015); as such, LUTS patients with elevated BMI and signs suggestive for metabolic syndrome may benefit from lifestyle changing involving dietary interventions (Gratzke et al., 2015). In addition, the motor/sensory functions of the perineum and the lower limb should be assessed to rule out neurologic alterations.

As the last step of the physical assessment, a digital rectal examination (DRE) should be performed. **DRE has a double aim: (1) to obtain a baseline estimation of prostate volume (PV), which is a useful parameter throughout the clinical decision-making process; and (2) to exclude the presence of palpable nodules or any increased consistency that may signal the presence of PCa.**

The sensitivity of DRE in detecting PCa is low, with historical series showing PCa detection rates on biopsy as low as 40% to 50% in the era before prostate-specific antigen (PSA) testing among patients with positive DRE findings (Chodak et al., 1989). More recently, positive predictive values of abnormal DRE findings have been reported, ranging from 6% to 33% (Bozeman et al., 2005). However, in the European Randomized Study of Screening for Prostate Cancer (ERSPC), DRE was found to be useful in combination with PSA testing to decrease overdiagnosis of cancer (Gosselaar et al., 2008).

The PV tends to be underestimated by DRE, because of impalpable areas on the bilateral prostate (Roehrborn 1998), especially for PV greater than 30 mL. However, Bosch et al. (2004) reported a positive predictive value of 69.2% for a 30-mL cutoff level and 99.8% for a 50-mL cutoff level; similarly, a positive predictive value of 94.1% for PV less than 30 mL has been associated with the presence of a flat/normal prostate on DRE (Yamamoto et al., 2017). In this context, although PV does not correlate with LUTS severity or with the degree of obstruction (Roehrborn et al., 1986; Simonsen et al., 1987), the 30- and 50-mL cutoffs could be useful to predict treatment response and the risk for disease progression (Roehrborn et al., 2001).

Finally, anal sphincter tone should be assessed while a DRE is being performed: a flaccid or spastic sphincter may be a sign of neurologic disorders (Gratzke et al., 2015; McVary et al., 2011).

Frequency-Volume Charts and Bladder Diaries

The assessment of the storage component of LUTS should rely on the use of urinary diaries, providing the caregiver with an objective estimation of the patient's urinary behavior.

The ICS has defined three types of urinary diaries (Abrams et al., 2002), based on recorded parameters:

- Micturition charts, recording the time of each micturition for at least 24 hours
- Frequency-volume charts (FVCs), recording the voided volume and the time of each micturition during day and night hours for 24 hours
- Bladder diaries, recording the time of micturition, voided volume, and additional information such as fluid intake, incontinence episodes, degree of incontinence, pad usage, and degree of urgency

With these tools, it is possible to estimate the so-called *24-hour voiding frequency*, the fraction of urine production during the night (nocturnal polyuria index), and the mean voided volume.

International clinical guidelines advise that FVCs (or their derived forms) should be used during the basic evaluation of patients with prevalent storage LUTS or nocturia (Abrams et al., 2013; Gratzke et al., 2015; McVary et al., 2011). FVCs are considered as a mainstay for the assessment of nocturia (Cornu et al., 2012). Nocturia has been defined as “the complaint that an individual has to wake at night one or more times to void” (Abrams et al., 2002), and belongs to the storage component of LUTS. FVCs are regarded as more accurate than recall-based measures, such as the IPSS questionnaire, in terms of nocturia diagnosis (Yap et al., 2007) and to characterize its underlying mechanism (Weiss et al., 2012). However, there is a substantial heterogeneity concerning the content, format, and the duration of urinary diaries in the literature; moreover, a bladder training effect has been associated with the use of FVCs, thus leading to biased measurements (Vaughan et al., 2014). In this context, instructing patients not to change their routines and teaching them how to complete the FVCs might reduce these types of measurement error. As a main issue of controversy, the exact duration of the assessment should be carefully selected, given the reported evidence of reduced adherence associated with a prolonged assessment (7 days), and an increase in the reliability of measures caused by a higher number of recording days (Bright et al., 2011). In a systematic review aimed at identifying the proper duration of an FVC assessment, Yap et al. (2007) recommended the use of FVCs with a duration of 3 days or more. Bright et al. (2014) conducted a phase II prospective study aimed at validating urinary diaries according to the psychometric validation protocol of the ICS: they assessed the optimal diary duration by comparing a 4-day diary with diaries of shorter durations, and concluded that 3 days should be considered as a reference duration.

Laboratory Tests

Laboratory tests are used both as part of the basic patient's evaluation and as secondary investigations in selected clinical contexts (Gratzke et al., 2015; McVary et al., 2011).

Urinalysis

The use of a dipstick test and/or the microscopic evaluation of urine samples is suggested in all patients complaining of LUTS as a part of the baseline evaluation (Gratzke et al., 2015; McVary et al., 2011). This costless and readily available tool could provide the physician with useful information to help the differential diagnosis and to prompt secondary diagnostic tests, when needed.

The presence of pyuria and a positive nitrite test on urinalysis suggest an underlying urinary tract infection (UTI), which could be responsible for reported patient symptoms. However, in a prospective study assessing the accuracy of dipstick urinalysis and microscopic pyuria in detecting UTI among patients presenting for painless LUTS, sensitivities of only 56%, 10%, and 56% for 10^5 cfu/mL leukocyte esterase, the presence of nitrites, and microscopic pyuria, respectively, were reported (Khasriya et al., 2010).

Moreover, the presence of gross hematuria should prompt the physician to exclude the presence of bladder cancer; likewise, proteinuria, glucosuria, and ketonuria detected by urinalysis could be considered a sign of diabetes mellitus, potentially correlated with LUTS.

Urine cytology should always be requested in men with severe storage symptoms and dysuria, especially if they have a smoking history.

Prospective controlled trials assessing the clinical benefit of urinalysis for the basic evaluation of patients with LUTS are currently lacking. However, the general expert consensus is that the benefits of such a readily available diagnostic test outweigh the costs.

Prostate-Specific Antigen

The value of PSA testing among patients presenting for LUTS is multiple: assess the risk and eventually rule out the presence of PCa; estimate PV; and predict BPH-related outcomes.

BPH and PCa are two distinct conditions that may often overlap: autopsy studies provided evidence for the coexistence of PCa and BPH in 83% of cases (Bostwick et al., 1992). Moreover, in a large European population-based study including 3 million men, a significant association between LUTS and the risk for subsequent diagnosis of PCa was reported, with hazard ratios (HRs) ranging from 2.2 to 4.5 (Ørsted et al., 2011). However, these results could have been affected by a detection bias related to a higher frequency of medical assessments for men complaining of LUTS compared with controls, which could result in a greater likelihood of testing and diagnosis of PCa. Indeed, in a prospective study assessing the association between LUTS and PCa in 1922 men, those treated for LUTS were more likely to undergo prostate biopsy (HR, 2.4; 95% CI, 1.7 to 3.3), thus resulting in an increased PCa diagnosis rate for men younger than 65 years of age (Weight et al., 2013). Moreover, in the placebo arm of the Prostate Cancer Prevention Trial (PCPT), there was no association between LUTS and PCa (Schenk et al., 2011).

Outlet obstruction is likely a late event in the natural history of PCa, infrequently occurring in the modern era (Bhindi et al., 2017). Serum PSA trends over time (PSA velocity), measurement of free versus complexed PSA, PSA density, and new markers such as PCA3 and p2PSA (Lazzeri et al., 2013) may help to improve PSA testing specificity in men with BPH. In this context, the benefits and risks of PSA testing always should be discussed with every patient, considering the possibility of false-positive and false-negative results and the complications possibly associated with prostatic biopsy. **Current international clinical guidelines suggest measurement of PSA if a diagnosis of PCa will change LUTS management,** excluding, for instance, those men with a life expectancy of less than 10 years (Gratzke et al., 2015; McVary et al., 2011).

Data from pooled analysis of placebo-controlled trials showed that the PSA test has an area under the curve of 0.76 to 0.78 for various PV thresholds (30 mL, 40 mL, 50 mL) (Bohnen et al., 2007). Moreover, a PSA level of more than 1.6 ng/mL, more than 2.0 ng/mL, and more than 2.3 ng/mL was associated with a sensitivity of 70% and a specificity of 65% to 70% in terms of detection of PV greater than 40 mL for patients in their 50s, 60s, and 70s, respectively (Bohnen et al., 2007). Comparable accuracy in the estimation of PV was reported for free PSA (Kayikci et al., 2012). Both PSA forms were found to predict transrectal ultrasound (TRUS)-measured PV to within ±20% in more than 90% of cases (Morote et al., 2000).

PSA level is also a predictor of BPH-related outcomes. In a large randomized trial, PSA level correctly predicted changes in terms of LUTS, QoL, and maximum urinary flow rate (Qmax) (Roehrborn et al., 1999). Moreover, baseline PSA level was found to be a consistent predictor of acute urinary retention (AUR) and BPH-related surgery in the placebo arm of large long-term randomized controlled studies (McConnell et al., 2003; Roehrborn et al., 2008a). In addition, a positive predictive value of 68% for the diagnosis of BOO has been reported to be associated with total PSA levels (Lim et al., 2006).

Finally, caution should be paid in patients treated with 5α-reductase inhibitors (5ARIs), given that serum PSA level is reduced by 40% to 50% after 12 months of treatment (Guess et al., 1993). Failure to establish a baseline (pretreatment) PSA level may complicate the interpretation of future PSA assessments.

Renal Function Assessment

The assessment of renal function based on serum creatinine level or estimated glomerular filtration rate is not routinely suggested in patients with LUTS (Gratzke et al., 2015; McVary et al., 2011)**. As a whole, AUA guidelines no longer recommend a routine renal function assessment, but EAU guidelines suggest assessment of serum creatinine level if renal impairment is suspected on the basis of medical history or when surgical treatment is considered.**

An elevated serum creatinine level was found in 11% of patients presenting for LUTS (Gerber et al., 1997). In a more recent series, 161 of 2741 LUTS patients (5.9%) received a diagnosis of chronic kidney disease (Hong et al., 2010). In addition, in the Medical Therapy of Prostatic Symptoms (MTOPS) trial, less than 1% of men with LUTS experienced kidney failure over a period of 4 years (McConnell et al., 2003). Decreased peak flow rate (Qmax) along with a history of hypertension and/or diabetes was associated with chronic kidney disease in men with LUTS (Hong et al., 2010). Similarly, Qmax significantly correlated with estimated glomerular filtration rate in middle-aged men with moderate-to-severe LUTS, whereas PV, postvoid residual (PVR) volume, and IPSS did not (Lee et al., 2013). Patients with renal insufficiency have been found to have increased risk for complications after BPH surgery (Mebust et al., 1989).

Instrumental Investigations

Instrumental diagnostic modalities have emerged as potential useful tools to better characterize the causes of LUTS. However, although some of these tests are considered part of the basic routine assessment of male LUTS, others should be suggested only in specific cases, with the specific aim to help the physician to choose the right treatment and to allow a correct differential diagnosis between BPE and other conditions (Gratzke et al., 2015; McVary et al., 2011).

Postvoid Residual Volume

PVR volume is defined as the volume (mL) of urine left in the bladder at the end of micturition. Currently, there is no standardized definition for a normal PVR volume. **In clinical practice, a PVR volume of less than 30 mL is usually considered nonsignificant, whereas PVR volume persistently greater than 50 mL could be regarded as important** (Asimakopoulos et al., 2016). Significant chronic PVR volume has been widely defined as a volume more than 300 mL (Asimakopoulos et al., 2016).

Of clinical relevance, there is a large within-subject variability in the PVR volume assessment: a wide volume variation was reported in 66% of cases when three measurements were done on the same day (Birch et al., 1988).

In 2014, the ICS Urodynamics Committee established a guideline for the correct assessment of PVR volume (Asimakopoulos et al., 2016) stating that (level of evidence 3):

- The interval between voiding and PVR volume measurement should be of short duration.
- Although transurethral catheterization is considered the gold standard to assess PVR volume, it could be associated with patient discomfort and the risk for UTIs and urinary tract trauma.
- **The ultrasound bladder volume measurement should be**

> **used to assess PVR volume and can be performed with either a real-time transabdominal ultrasound scanner or a portable bladder scanner.**

The presence of an abnormal PVR volume is not highly correlated with BOO. Indeed, an abnormal PVR volume could be the consequence of either BOO or DUA. In this context, the diagnostic accuracy of PVR volume measurement has a positive predictive value of 63% and a negative predictive value of 52% to detect BOO (Oelke et al., 2007). At the same time, a PVR volume of 200 to 300 mL may indicate DUA and predict a less favorable response to LUTS treatment according to expert opinion (Asimakopoulos et al., 2016).

In two large randomized controlled trials (RCTs), a high PVR volume was significantly associated with the risk for LUTS deterioration: a PVR volume of more than 39 mL and more than 93 mL was associated with a 4-point or more increase of the IPSS in the MTOPS trial and in the Alfuzosin Long-Term Efficacy and Safety Study (ALTESS), respectively (McConnell et al., 2003; Roehrborn et al., 2008a). Conversely, PVR volume did not correlate with the need for BPH-related surgery.

The association between PVR volume and AUR has also been assessed. Mochtar et al. (2006), for instance, failed to find an association between AUR and PVR volume (either above or below 300 mL) in men treated with α-blockers or watchful waiting (WW). However, a PVR volume of at least 500 mL was previously associated with a 3.6 times higher risk for AUR recurrence (Klarskov et al., 1987). Moreover, in a 10-year longitudinal study including 1068 men with BOO, PVR volume was not a predictor of AUR (Thomas et al., 2005a). Conversely, findings from the MTOPS trial showed that the increase of PVR volume over time correlated with increased risk for AUR in the placebo group (Roehrborn 2008).

Large or persistent PVR volume has also been associated with UTI in males at risk (e.g., children, patients with neurologic alterations or diabetes). Conversely, this association was not demonstrated in adults without risk factors for UTIs (Asimakopoulos et al., 2016).

In conclusion, **PVR volume assessment is suggested both during basic workup and during the follow-up of patients with LUTS. Men with significant PVR volume should be monitored closely if they elect to have nonsurgical therapy** (Gratzke et al., 2015; McVary et al., 2011).

Uroflowmetry

Uroflow measurement is a basic noninvasive urodynamic test providing an objective and quantitative indication of the integration of bladder function and outlet. It is based on the electronic recording of the free urinary flow rate throughout the course of micturition. The main parameters provided by uroflowmetry are Qmax (or peak urinary flow rate [PFR]), voided volume, and flow pattern (Fig. 145.1). Average flow rate is considered less accurate than Qmax to detect BOO (McConnell et al., 1994).

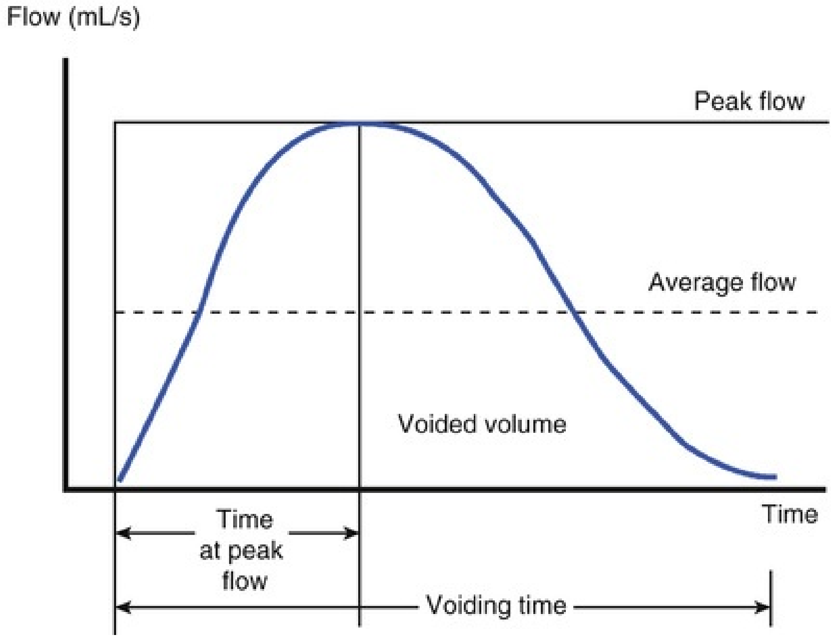

FIG. 145.1 Uroflometry graph; the peak flow rate *(PFR),* the flow pattern, and the voided volume are the main parameters of the test.

There is substantial within-subject variation in terms of uroflowmetry results among measurements taken either on the same day or on consecutive days (Jørgensen et al., 1992; Kranse and van Mastrigt, 2003). Single free-flow measurements tend to underestimate achievable Qmax levels (Reynard et al., 1996). Indeed, Qmax is greatly influenced by the voided volume: flow rate measurements are inaccurate if the voided volume is less than 125 to 150 mL (Gratzke et al., 2015; McConnell et al., 1994; McVary et al., 2011). Moreover, there is evidence of possible changes in the uroflow parameters associated with different voiding positions (Choudhury et al., 2010; Yamanishi et al., 1999). According to ICS recently published good urodynamic practices and terms

(Rosier et al., 2017), patients should be allowed to undergo uroflowmetry in their own preferred position. Furthermore, given the correlation between uroflow parameters and patient cooperation and emotion, uroflowmetry findings should be clinically interpreted if the voiding per se has been representative according to the patient's opinion (Rosier et al., 2017). Repetition of the test is suggested to increase the reliability of the results, especially for voided volumes below 150 mL (Gratzke et al., 2015; McVary et al., 2011; Rosier et al., 2017).

The role of uroflowmetry in the diagnosis of BOO has been widely investigated, and is limited by its inability to distinguish between a low flow rate caused by BOO, DUA (which is present in 9% to 48% of men undergoing urodynamic evaluation for non-neurogenic LUTS) (Osman et al., 2014), or both. To date, several studies specifically assessed the accuracy of uroflowmetry for BOO detection. The results differed considerably according to the threshold values applied. In the largest published series, including 1271 men recruited at 12 centers, a Qmax threshold value of 10 mL/s had a 70% specificity, a positive predictive value of 70%, and a sensitivity of 47% for detection of BOO. Increase of the threshold to 15 mL/s was associated with a specificity of 38% and a sensitivity of 82% (Reynard et al., 1998). The EAU Male LUTS Guidelines Panel performed a systematic review of published studies assessing the accuracy of noninvasive tests in 2580 men with suspected BOO. They showed that a 10 mL/s cutoff threshold value to define BOO was associated with a positive predictive value of 74.3% and a negative predictive value of 68% (Malde et al., 2017). The panel confirmed that uroflowmetry alone is unsuitable to detect and properly quantify BOO (Gratzke et al., 2015; Malde et al., 2017).

According to expert opinion, a PFR cutoff of 15 mL/s could be used to define outlet obstruction in clinical practice (McConnell et al., 1994)**. However, a PFR of less than 15 mL/s does not differentiate between obstruction and bladder decompensation.**

International clinical guidelines consider uroflowmetry as on optional test in the assessment of patients with LUTS, although its use is recommended before any active treatment (Gratzke et al., 2015; McVary et al., 2011).

Finally, uroflowmetry is considered a valuable test for monitoring treatment outcomes and correlating symptoms with objective findings.

Urodynamics

The term *urodynamics* refers to a diagnostic test allowing the assessment of lower urinary tract function via the measurement of relevant physiologic parameters (Rosier et al., 2017). Invasive urodynamic testing involves the use of catheters or transducers inserted into the bladder and/or other body cavities, whereas noninvasive urodynamic tests are performed without the use of catheters (e.g., uroflowmetry, PVR volume, penile compression–release test, penile cuff).

The invasive urodynamic test is the gold standard for the assessment of LUTS pathophysiology and it is used to identify DO, DUA, low bladder compliance, and BOO. The examination is characterized by two distinct evaluations investigating the storage and voiding phase of micturition: the filling cystometry and the pressure-flow study (PFS).

The term *videourodynamics* refers to the use of synchronous radiographic imaging and filling the bladder with contrast medium while cystometry and a PFS are performed. This test allows one to obtain additional anatomic information by showing the presence of eventual alteration of the bladder profile (diverticula, trabeculation), of vesicoureteral reflux, or of alterations of the pelvic floor activity. No clear recommendation is currently provided regarding the use of videourodynamics (Abrams et al., 2013; Gratzke et al., 2015).

Filling Cystometry

Cystometry allows the assessment of the storage phase. It is characterized by a continuous fluid filling of the bladder through a transurethral catheter, with a concomitant measurement of intravesical and abdominal pressure and the display of the detrusor pressure (Rosier et al., 2017). Patients are instructed before the test on how to report sensations: during the filling phase, parameters such as first sensation of filling, first desire to void, and strong desire to void are recorded. **In patients with LUTS suggestive of BOO, the main goal of this test is the detection of involuntary detrusor contractions, which may identify DO** (Gratzke et al., 2015). In a study assessing DO in a cohort of 1418 patients with suspected BPH, up to 60.9% of them showed DO on filling cystometry. Age and obstruction degree were significantly associated with DO (Thomas et al., 2005b).

The diagnosis of DO could be useful to identify patients who may benefit from the use of anticholinergic drugs either alone or in combination with other treatments.

Pressure-Flow Study

The PFS allows assessment of the voiding phase. It is defined as the measurement of the intravesical and abdominal pressure while uroflowmetry is performed with a transurethral catheter in place (Rosier et al., 2017). The findings of this test are depicted in a plot of the flow rate on the *x*-axis and the synchronous detrusor pressure on the *y*-axis. **The joint evaluation of detrusor pressure and flow rate allows the diagnosis of either BOO (characterized by impaired flow rate along with an increased detrusor pressure) or DUA (characterized by the impairment of both flow rate and detrusor pressure)**.

The prevalence of DUA in men with LUTS ranges between 9% and 48% (Osman et al., 2014). The presence of DUA was associated with long-term symptomatic failure and decreased flow rates after BPH surgery in a large cohort of 1068 men followed up for a mean of 13 years after treatment (Thomas et al., 2005a). Moreover, the bladder contractility index (obtained after PFS) was reported neither to improve after surgery nor to decrease over time in patients conservatively managed for BOO/BPH (Al-Hayek et al., 2004), suggesting that detrusor contractility is not influenced by active treatment and the duration of BOO.

No RCTs specifically compared the accuracy of noninvasive tests (e.g., uroflowmetry and PVR volume) with PFS in predicting treatment outcomes in patients with BOO. However, a similar randomized trial was ongoing in the United Kingdom at the time this chapter was written.

As invasive diagnostic modalities, both the European and the American guideline panels do not routinely suggest the use of urodynamic tests to assess men with LUTS (Gratzke et al., 2015; McVary et al., 2011). However, **PFS is suggested before invasive treatments in some specific scenarios:**

- **Patients with previously unsuccessful invasive treatments for LUTS**
- **Patients who cannot void more than 150 mL**
- **Patients with PVR volume greater than 300 mL**
- **Patients older than 80 years of age with predominantly voiding LUTS**
- **Patients younger than 50 years of age with predominantly voiding LUTS**

Moreover, the AUA consensus panel stated that PFS may be performed in patients with a Qmax greater than 10 mL/s before surgical treatment is considered (Abrams et al., 2013).

Finally, urodynamic tests should be considered for men with suspected underlying neurologic conditions or with a history of pelvic surgery.

Imaging

The role of imaging in the management of LUTS is mainly restricted to candidates for surgery and only in selected cases before medical treatment. Novel ultrasound parameters assessing the morphology of the bladder and the prostate are currently under evaluation in terms of BOO diagnosis.

Upper-Tract Imaging

The routine assessment of the upper tract with ultrasonography is not recommended in patients with LUTS (Gratzke et al., 2015; McVary et al., 2011). Indeed, the presence of kidney abnormalities in patients with LUTS has been infrequently reported. In a population of 6102 patients evaluated in 25 studies by intravenous urography before prostate surgery, only 7.6% were found to have hydronephrosis (McConnell et al., 1994). Similarly, Koch et al. (1996) reported a 2.5% prevalence of hydronephrosis in 665 patients with BPH, along with 11.7% of patients with renal cysts and 0.18% of patients with renal cell carcinoma. According to these findings, **imaging assessment of the upper tract is currently suggested for patients with LUTS combined with an elevated serum creatinine level or large PVR volumes. Likewise, patients with a history of hematuria, UTI, urolithiasis, or prior urinary tract surgery should also be assessed with abdominal ultrasonography** (Andrews et al., 2002; Gratzke et al., 2015).

Intravenous urography is no longer used in this clinical setting.

Prostate and Bladder Imaging

Imaging of the prostate is usually performed through suprapubic ultrasonography or TRUS. TRUS imaging is considered the method of choice to define PV, which can be a valuable parameter driving the choice of treatment and serving as a predictor of treatment outcomes.

Candidates for treatment with 5ARIs should be evaluated for PV, as treatment outcomes have been related to the baseline gland volume (McConnell et al., 2003; Roehrborn et al., 2010). The PV estimated by TRUS imaging was a predictor of BPH progression and invasive treatment in the MTOPS trial (McConnell et al., 2003). Similarly, data from the placebo arm of the ALTESS showed that men with a PV greater than 49 mL had a 3.2% risk for AUR compared with those with a PV of 49 mL or less (Roehrborn, 2008). Likewise, the Olmsted County study found an increased risk for AUR with increasing prostate size in a cohort of 2115 men (Jacobsen et al., 1997).

In a retrospective study of 521 patients, the sensitivity and specificity of PV in the detection of BOO were 49% and 32%, respectively, for a cutoff of 40 mL (Eckhardt et al., 2001). These results confirmed previous evidence of a weak correlation between PV and BOO (Rosier et al., 1995).

Ultrasound-based estimation of PV (either suprapubic or TR) should be routinely performed before any BPH surgery so as to help the physician in choosing the most appropriate technique (Gratzke et al., 2015; McVary et al., 2011). Moreover, the detection of a third prostate lobe protruding into the bladder could guide the choice of treatment in patients scheduled for minimally invasive approaches (Gratzke et al., 2015).

Intravesical prostatic protrusion (IPP) is defined as the distance from the tip of the protruding prostate to the base at the circumference of the bladder, and can be assessed by suprapubic ultrasound imaging in the sagittal plane. According to the theory that a greater IPP would cause a greater restriction of the proximal urethra, this parameter has been used as a noninvasive tool for the diagnosis of BOO (Gratzke et al., 2015). The IPP can differ according to the bladder volume, and should be estimated with a volume of 100 to 200 mL of urine in the bladder (Yuen et al., 2002). In a cohort of 2115 men with LUTS, a high IPP grade (>10 mm) was associated with a higher probability of medical treatment over time (Lieber et al., 2009); moreover, in a meta-analysis including patients from five studies, the median sensitivity and specificity of IPP for the detection of BOO were 67.8% and 74.8%, respectively, with a positive predictive value of 73.8% and a negative predictive value of 69.3% for a cutoff of 10 mm (Malde et al., 2017). Similarly, IPP showed good overall accuracy in predicting the outcome of a trial without catheter (TWOC) after AUR (Mariappan et al., 2007). However, **given the wide variability in the threshold values used and in terms of the method of assessment, there is currently no clear recommendation for using IPP as a noninvasive alternative to PFS to diagnose BOO.**

The ultrasound assessment of the bladder provides two additional parameters that are useful for the detection of BOO. As BOO leads to hypertrophy of the bladder wall, the bladder wall thickness (BWT) is defined as the entire diameter of the bladder wall measured from the hyperechogenic mucosa and hyperechogenic adventitia, whereas the detrusor wall thickness (DWT) is defined as the distance between the hypoechogenic detrusor sandwiched between the hyperechogenic mucosa and hyperechogenic adventitia (Arnolds et al., 2009). The accuracy of both measures in detecting BOO is higher than that of Qmax, PVR volume, PV, or symptom severity (Malde et al., 2017). Furthermore, pooled data analysis showed a median sensitivity of 82.7% and a median specificity of 92.6% for a BWT threshold of 2 mm (Malde et al., 2017). However, **because of the multifactorial nature of bladder wall hypertrophy and the lack of well-designed studies assessing the accuracy of these measures, a recommendation for the use of BWT/DWT for the diagnosis of BOO cannot be currently made.**

Recently, the ultrasound-estimated bladder weight (UEBW)—calculated using a specific ultrasound instrument as the product of bladder surface area (BWT) and bladder muscle-specific gravity—has been suggested to provide a more reliable measure of bladder wall hypertrophy; indeed BWT is greatly influenced by bladder filling volume. Currently, only two studies have evaluated the accuracy of UEBW, using different threshold values and showing wide variation in the results (Malde et al., 2017).

Cystourethrogram

The voiding cystourethrogram provides both morphologic and functional information allowing the detection of bladder wall diverticula, vesicoureteral reflux, and urethral strictures. **The use of cystourethrogram is suggested as an additional diagnostic test when urethral strictures or bladder abnormalities are suspected** (Gratzke et al., 2015).

Cystourethroscopy

In the context of LUTS assessment, cystourethroscopy can provide information regarding the morphology of the prostate and bladder neck, and the detection of detrusor trabeculation at the level of the bladder wall or the presence of diverticula. However, **cystourethroscopy is neither useful for the diagnosis of BOO nor to determine the need for treatment.**

A poor correlation between BOO and cystourethroscopy findings has been widely reported. The largest and updated series on this topic assessed 492 men with voiding complaints who underwent urodynamic investigations and flexible cystourethroscopy (Ezz El Din et al., 1996). The authors categorized the degree of bladder trabeculations found on endoscopy as 0 for none, 1 for slight to moderate, 2 for severe, and 3 for severe with (pseudo)diverticula. A significant correlation between BOO severity and the degree of bladder trabeculation was observed. However, up to 15% of patients with BOO showed a normal bladder wall, and up to 8% had severe trabeculation and no evidence of BOO.

Clinical guidelines suggest the use of cystourethroscopy in the case of reported gross hematuria, history of bladder cancer, history of recurrent UTIs or urethral injury (to rule out urethral stenosis), or in the case of previous surgery of the prostate or urethra.

Moreover, cystourethroscopy could help physicians in choosing the proper surgical treatment: the presence of a prostatic middle lobe is an important parameter to assess when one is considering the use of microwave therapy or needle ablation (Gratzke et al., 2015; McVary et al., 2011). Similarly, in young patients with small PV and predominantly obstructive LUTS, the presence of bladder neck contracture should be excluded before surgery.

Other Noninvasive Tests

Noninvasive modalities for the diagnosis of BOO associated with BPH have been developed as an alternative to invasive urodynamic tests. The external condom catheter test and the penile cuff test (PCT) allow the measurement of detrusor pressure without the use of a urethral catheter, by assessing the equal urine pressure along the urethra (in the penile cuff) or at the external meatus (using an external condom catheter). In the PCT, the pressure needed to stop the flow of urine represents the bladder isovolumetric pressure, and is detected by a cuff placed around the penis (Griffiths et al., 2002). Pooled data analysis of seven studies investigating the diagnostic accuracy of the PCT showed a median sensitivity of 88% and a specificity of 70% in detecting BOO (Malde et al., 2017). A single study evaluated the accuracy of the external condom method, showing that BOO could be detected in up to 73% of patients with this method (Pel et al. 2002).

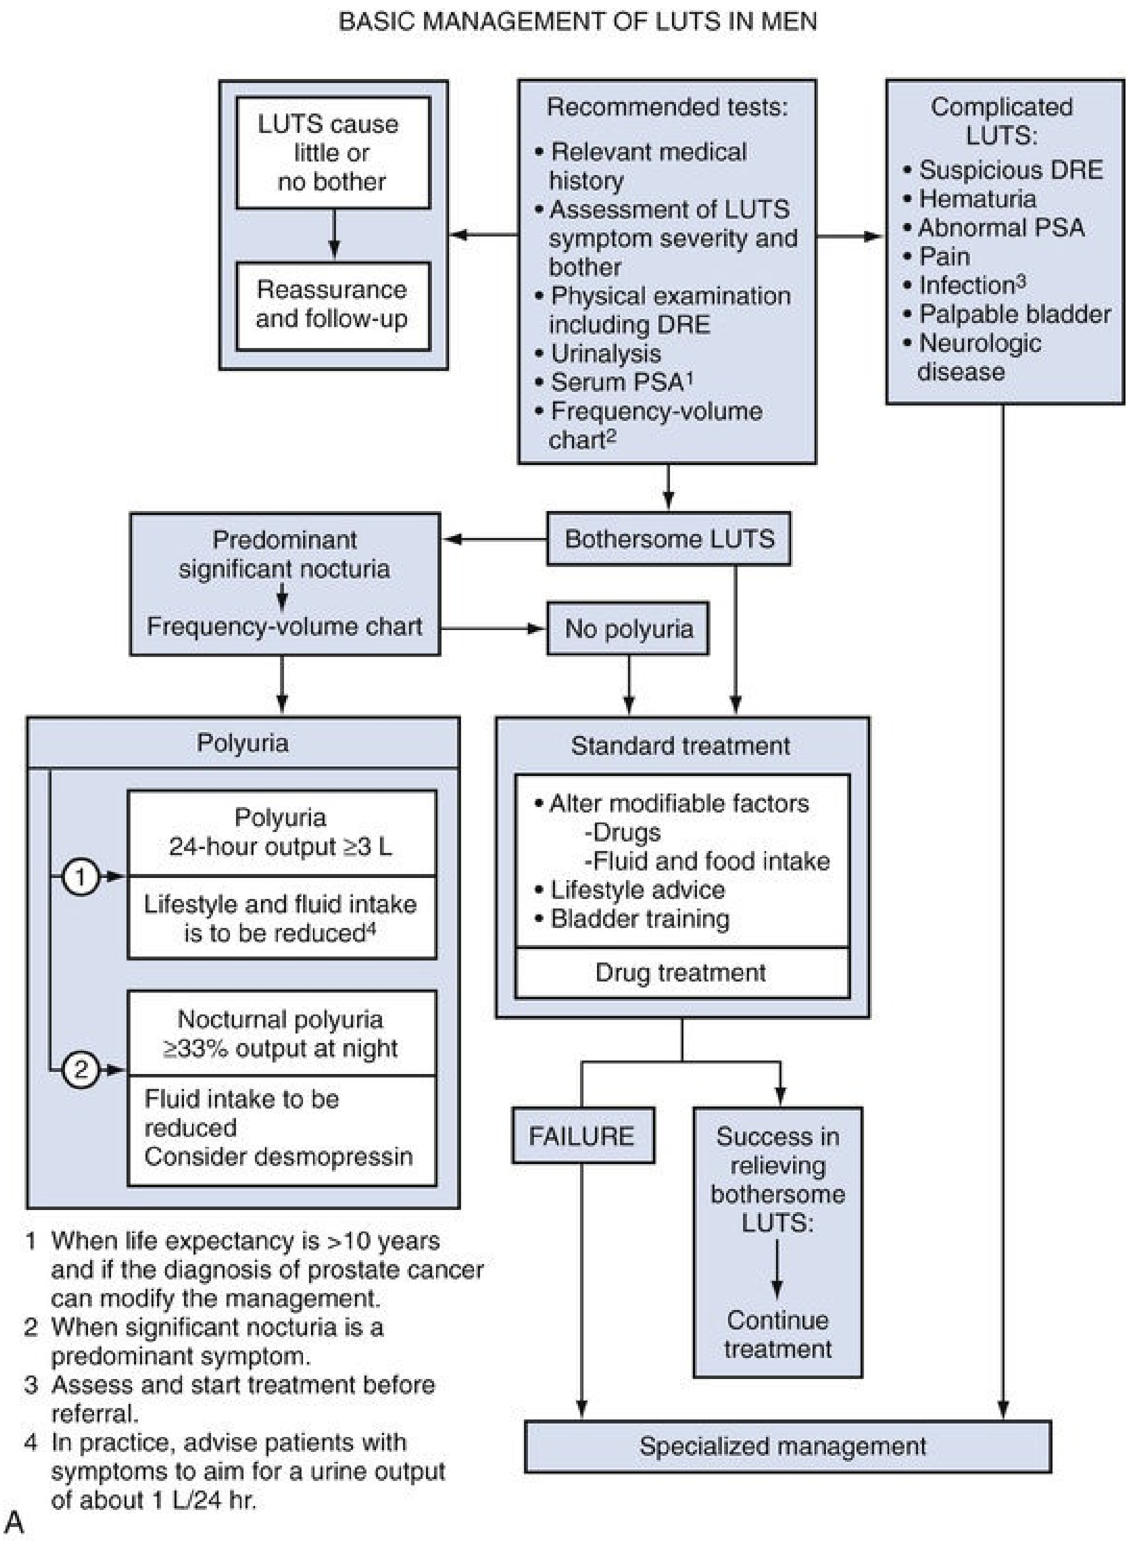
Among other imaging modalities, the use of Doppler ultrasound imaging was proposed to measure the reduction in detrusor blood flow associated with detrusor hypertrophy and BOO. Color Doppler ultrasound imaging allows the identification of arterial blood flow within the bladder wall and the calculation of the detrusor resistive index (RI) as the average of the RIs measured from three different sites in the bladder wall (Belenky et al., 2003); a positive predictive value of 95% and a negative predictive value of 57% have been reported in detecting BOO, with an RI greater than 0.05 (Belenky et al., 2003).

Near-infrared spectroscopy (NIRS) is based on the use of the infrared spectrum to monitor changes in the concentration of chromophores (oxyhemoglobin and deoxyhemoglobin) as a consequence of changes in detrusor oxygenation and hemodynamics, which usually occur with BOO during both the storage phase and voiding phase of the bladder. A mathematical algorithm has been developed for the assessment of BOO using NIRS parameters (Stothers et al., 2010), with data showing an 80% concordance rate with PFS (Macnab et al., 2008). Pooled data analysis from five studies showed a high diagnostic accuracy, with a median sensitivity of 85.7% and a specificity of 87.5% (Malde et al., 2017).

In 2017, the EAU guidelines expert consensus panel on the evaluation and treatment of LUTS provided a detailed analysis of the accuracy of noninvasive tests for BOO (Malde et al., 2017): the panel reported the highest accuracy for PCT, DWT, UEBW, and NIRS among all noninvasive modalities. However, because of the heterogeneity in the definition of BOO and the relatively small number of studies assessing each method, **the use of noninvasive tests for the diagnosis of BOO in patients with LUTS is currently not recommended as an alternative to PFS by the EAU.**

Practical Flowchart for the Evaluation of Patients With Lower Urinary Tract Symptoms

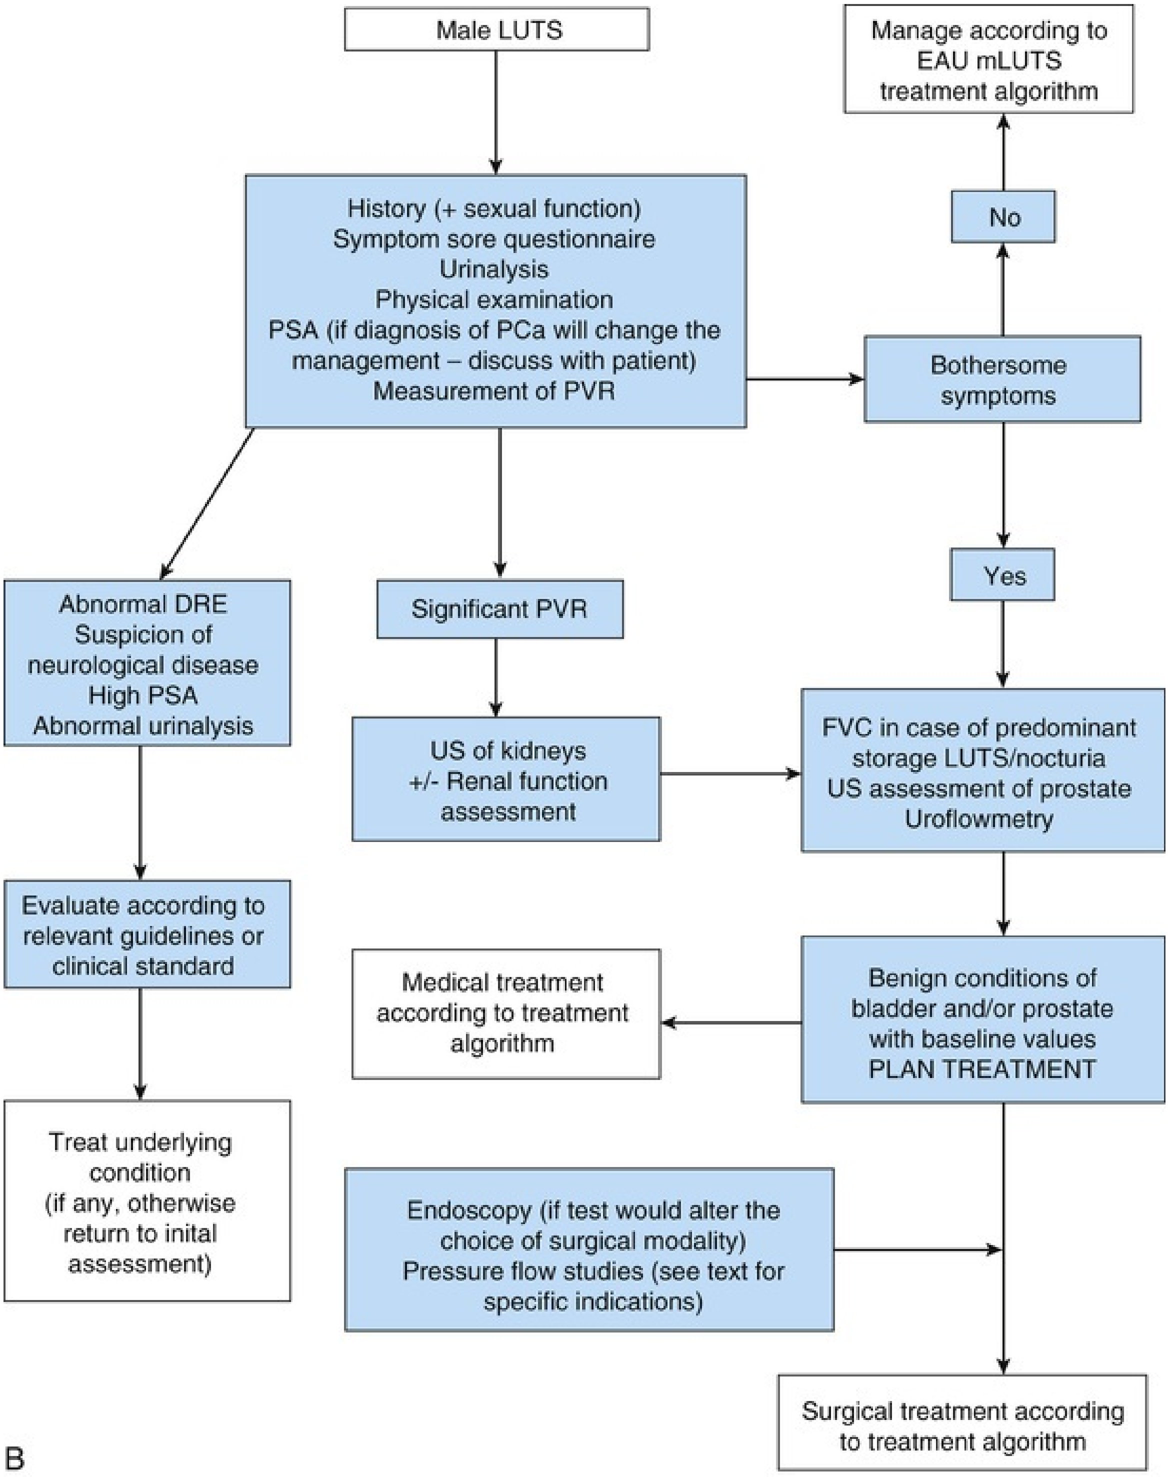
The EAU and AUA expert guidelines consensus panels have developed a practical algorithm to guide the physician in the management and evaluation of patients presenting with LUTS (Fig. 145.2).



BASIC MANAGEMENT OF LUTS IN MEN

LUTS cause little or no bother
Reassurance and follow-up
Recommended tests:
• Relevant medical history
• Assessment of LUTS symptom severity and bother
• Physical examination including DRE
• Urinalysis
• Serum PSA1
• Frequency-volume chart2
Complicated LUTS:
• Suspicious DRE
• Hematuria
• Abnormal PSA
• Pain
• Infection3
• Palpable bladder
• Neurologic disease
Bothersome LUTS
Predominant significant nocturia
Frequency-volume chart
No polyuria
Polyuria
1
Polyuria 24-hour output ≥3 L
Lifestyle and fluid intake is to be reduced4
2
Nocturnal polyuria ≥33% output at night
Fluid intake to be reduced
Consider desmopressin
Standard treatment
• Alter modifiable factors
-Drugs
-Fluid and food intake
• Lifestyle advice
• Bladder training
Drug treatment
FAILURE
Success in relieving bothersome LUTS:
Continue treatment
Specialized management
A

1 When life expectancy is >10 years and if the diagnosis of prostate cancer can modify the management.
2 When significant nocturia is a predominant symptom.
3 Assess and start treatment before referral.
4 In practice, advise patients with symptoms to aim for a urine output of about 1 L/24 hr.



Male LUTS
Manage according to EAU mLUTS treatment algorithm
History (+ sexual function)
Symptom sore questionnaire
Urinalysis
Physical examination
PSA (if diagnosis of PCa will change the management – discuss with patient)
Measurement of PVR
No
Bothersome symptoms
Yes
Abnormal DRE
Suspicion of neurological disease
High PSA
Abnormal urinalysis
Significant PVR
US of kidneys +/- Renal function assessment
FVC in case of predominant storage LUTS/nocturia
US assessment of prostate
Uroflowmetry
Evaluate according to relevant guidelines or clinical standard
Medical treatment according to treatment algorithm
Benign conditions of bladder and/or prostate with baseline values
PLAN TREATMENT
Treat underlying condition (if any, otherwise return to inital assessment)
Endoscopy (if test would alter the choice of surgical modality)
Pressure flow studies (see text for specific indications)
Surgical treatment according to treatment algorithm
B

FIG. 145.2 (A) International consensus guideline (2009) algorithm for management of lower urinary tract symptoms *(LUTS):* basic management. (B) Assessment algorithm for LUTS in men 40 years of age or older according to the European Urological Association consensus panel on LUTS treatment. *DRE,* Digital rectal examination; *FVC,* frequency–volume chart; *PCa,* prostate cancer; *PSA,* prostate-specific antigen; *PVR,* postvoid residual; *US,* ultrasound. (A, From Abrams P, Chapple C, Khoury S, et al.

Evaluation and treatment of lower urinary tract symptoms in older men. *J Urol* 189[1 Suppl]:S93–S101, 2013. B, From Gravas S, Bach T, Drake M, et al. EAU Guidelines on Management of non-neurogenic male LUTS, incl. benign prostatic obstruction [BPO]. Retrieved from: https://uroweb.org/wp-content/uploads/EAU-Guidelines-Management-of-non-neurogenic-male-LUTS-2016.pdf.)

According to the EAU guidelines, as a baseline assessment, the physician should collect a comprehensive medical history and examine the severity of symptoms and their impact on QoL by using dedicated tools; moreover, physical examination with DRE to estimate PV and exclude a locally advanced PCa should be conducted. Furthermore, urinalysis helps identify conditions other than BPH as a potential underlying cause of LUTS, and the assessment of PVR volume is a valuable noninvasive method to assess the risk for disease progression and to prompt further diagnostic evaluations if needed. Finally, a PSA test should be regarded as a basic diagnostic tool for patients with a life expectancy longer than 10 years, for whom the diagnosis of PCa would change the management.

According to the results of the baseline assessment, patients should undergo no further evaluation and treatment in the case of low-severity symptoms and normal findings from all performed tests, or should undergo additional investigations to help make the correct treatment choice. In this context, FVCs are useful for patients with predominantly storage phase LUTS; ultrasound assessment of the bladder and the prostate along with an uroflowmetry test is suggested when the severity of the symptoms requires either medical or surgical treatment. Moreover, upper urinary tract imaging and renal function evaluation should be considered for patients with elevated PVR volumes. Finally, although invasive urodynamic tests are the gold standard for the detection of BOO, they should be used in specific clinical scenarios suggestive of DO or DUA or after previous unsuccessful invasive treatments whenever surgical treatment is considered.

A comparable practical flowchart has been proposed by the AUA consensus panel, discriminating between a basic evaluation, possibly done by the general physician and based on the aforementioned baseline assessment tools, and specialized management performed by the urologist, with additional investigations for patients in whom non-BPH conditions are suspected and/or for those highly bothered by symptoms.

Key Points

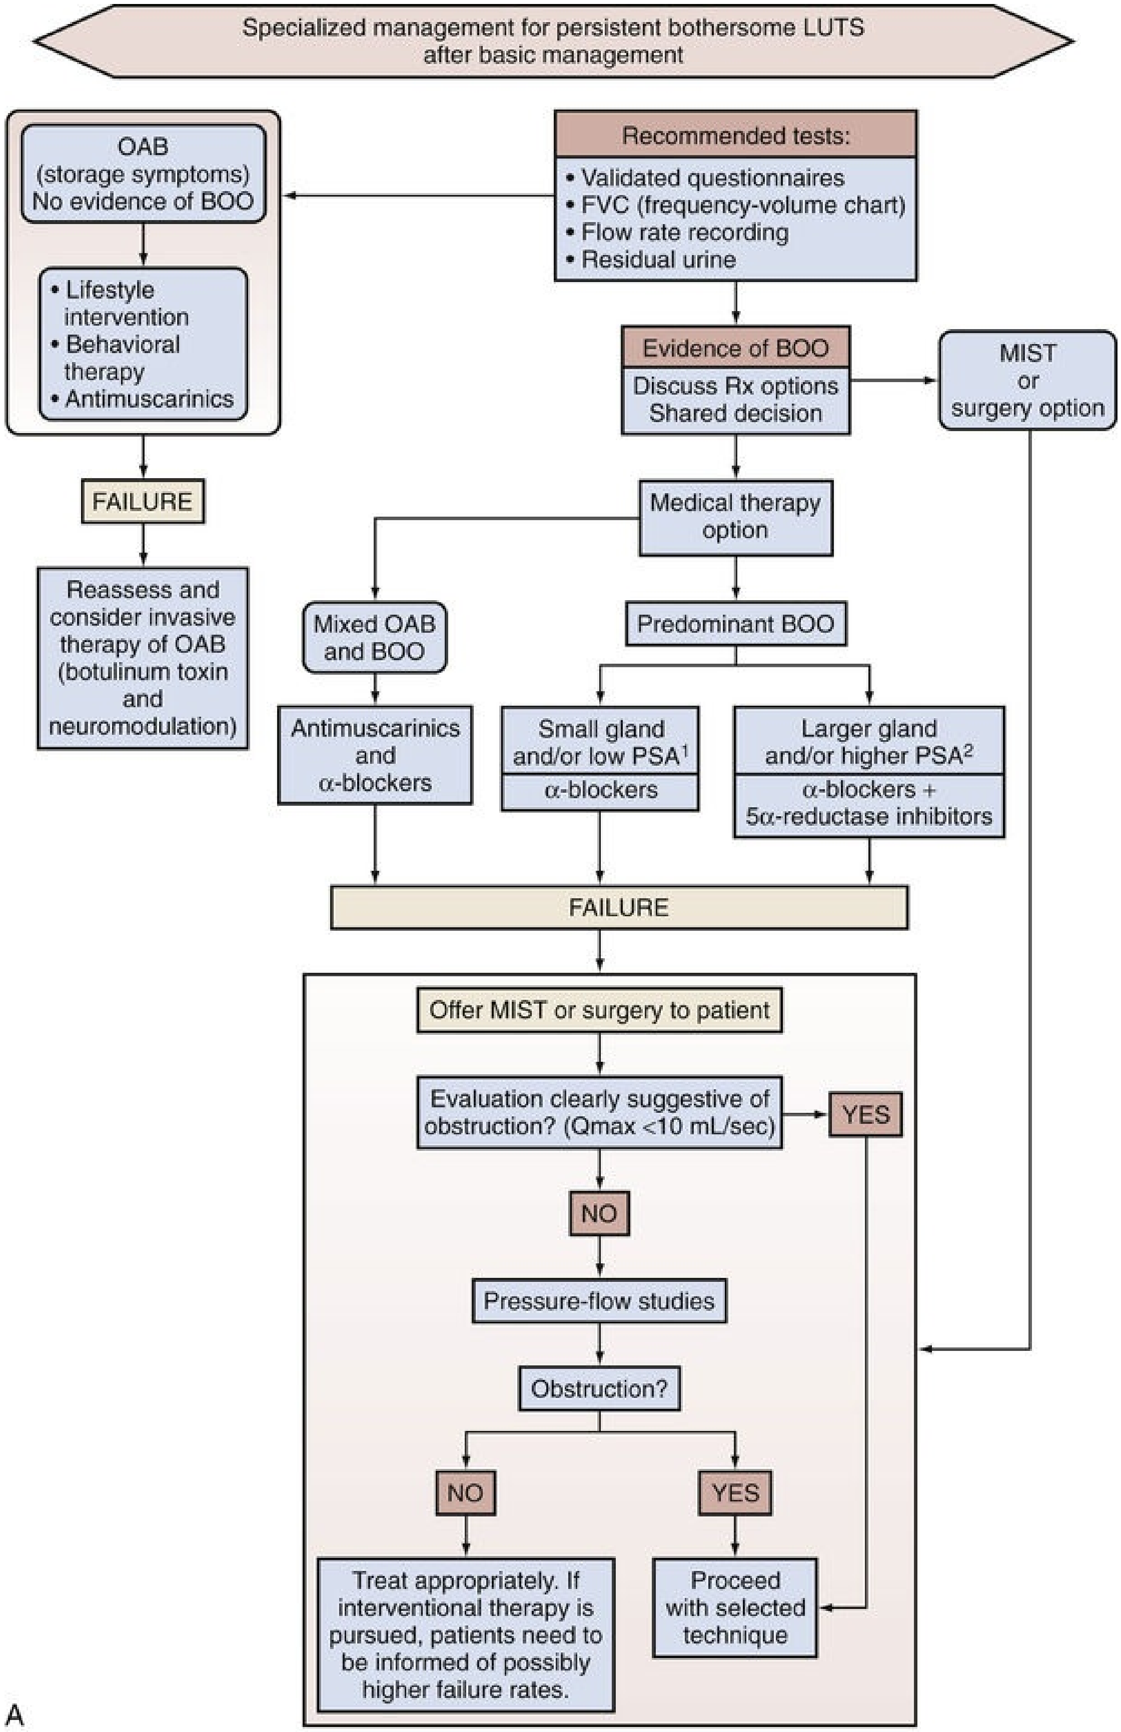
- Assessing symptom severity is the first step in the workup of patients with LUTS.
- The PSA test should be considered for patients with a life expectancy longer than 10 years.
- Ultrasound imaging and uroflowmetry should be performed for patients with moderate to severe symptoms.
- Invasive urodynamic tests should be considered if bladder motility alterations (e.g., DO, DUA) are suspected.

Management of Lower Urinary Tract Symptoms Caused by Benign Prostatic Enlargement

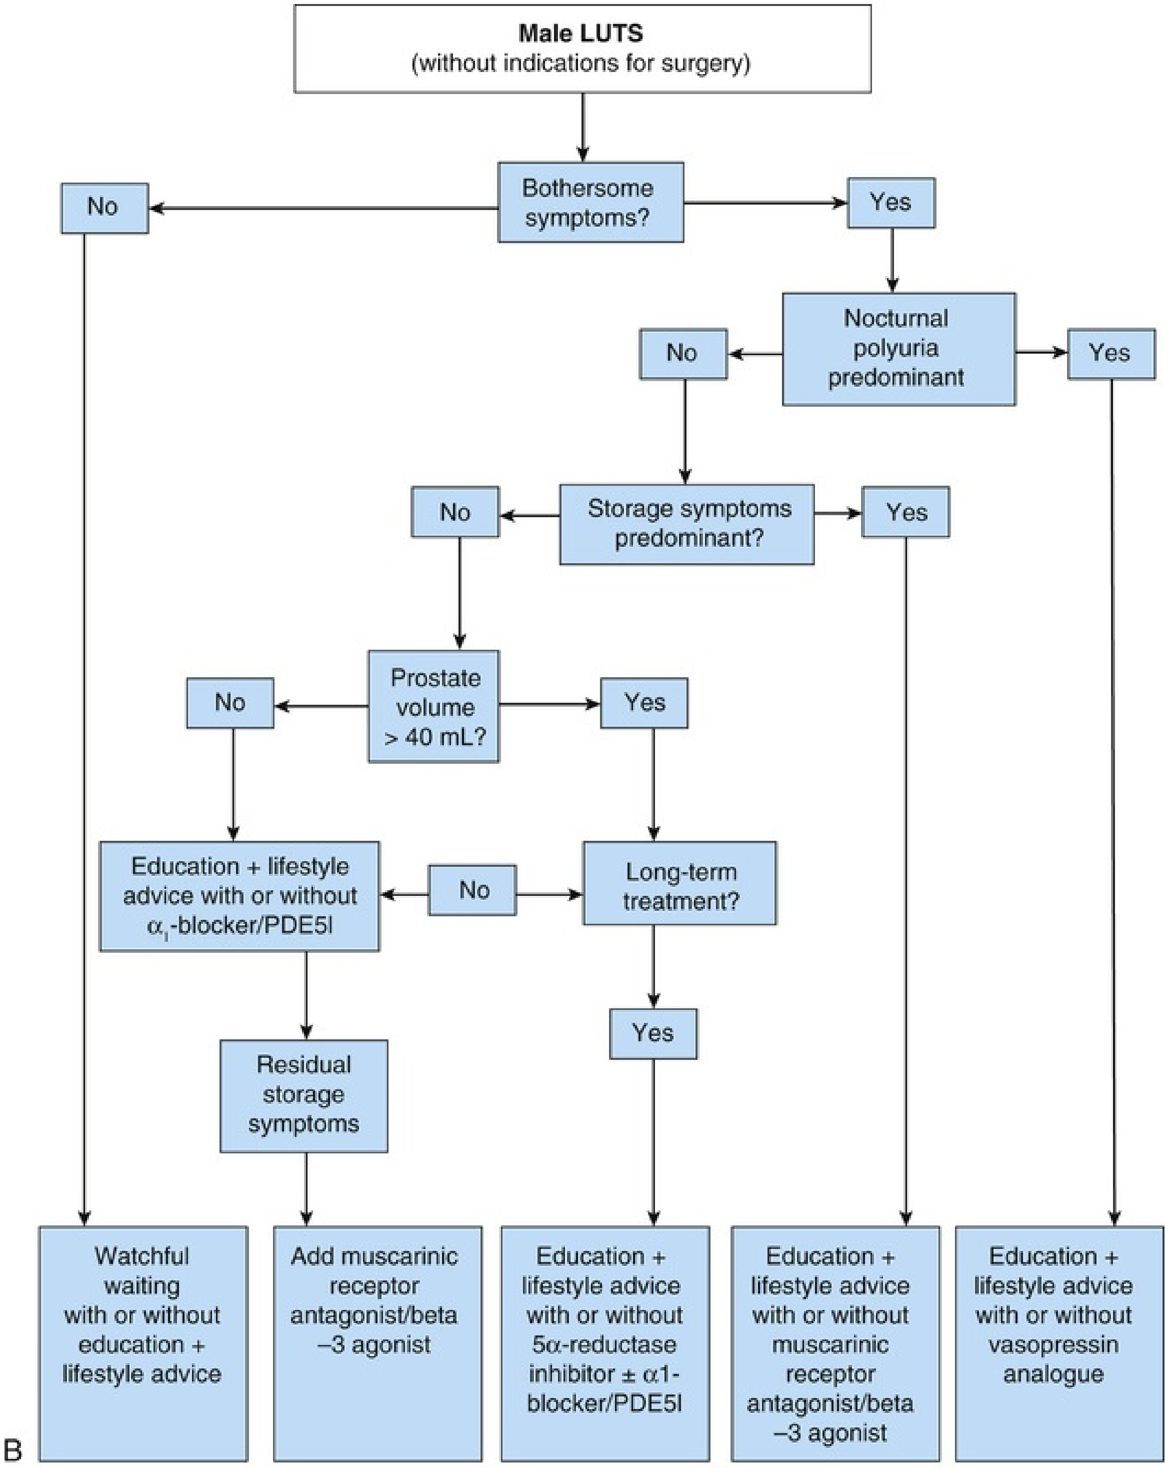
The therapeutic management of patients with LUTS is driven by the patient's clinical characteristics, findings of the baseline diagnostic assessment, and patient preferences (McVary et al., 2011; Oelke et al., 2013). Overall, two different therapeutic approaches could be adopted: a conservative approach or active management (involving either medical or surgical treatment).

Conservative Management

Both the AUA and EAU expert consensus panels suggest that patients with mild-to-moderate noncomplicated LUTS who are minimally bothered by their symptoms should be offered conservative management (McVary et al., 2011; Oelke et al., 2013) (Fig. 145.3; see Fig. 145.2). Complicating factors may be detected throughout the diagnostic assessment process and include the following:



Specialized management for persistent bothersome LUTS after basic management
OAB (storage symptoms) No evidence of BOO
• Lifestyle intervention
• Behavioral therapy
• Antimuscarinics
FAILURE
Reassess and consider invasive therapy of OAB (botulinum toxin and neuromodulation)
Recommended tests:
• Validated questionnaires
• FVC (frequency-volume chart)
• Flow rate recording
• Residual urine
Evidence of BOO
Discuss Rx options Shared decision
MIST or surgery option
Medical therapy option
Mixed OAB and BOO
Predominant BOO
Antimuscarinics and α-blockers
Small gland and/or low PSA1
α-blockers
Larger gland and/or higher PSA2
α-blockers + 5α-reductase inhibitors
FAILURE
Offer MIST or surgery to patient
Evaluation clearly suggestive of obstruction? (Qmax <10 mL/sec)
YES
NO
Pressure-flow studies
Obstruction?
NO
YES
Treat appropriately. If interventional therapy is pursued, patients need to be informed of possibly higher failure rates.
Proceed with selected technique
A



Male LUTS
(without indications for surgery)
Bothersome symptoms?
No
Yes
Nocturnal polyuria predominant
No
Yes
Storage symptoms predominant?
No
Yes
Prostate volume > 40 mL?
No
Yes
Education + lifestyle advice with or without α1-blocker/PDE5I
No
Long-term treatment?
Yes
Residual storage symptoms
Watchful waiting with or without education + lifestyle advice
Add muscarinic receptor antagonist/beta –3 agonist
Education + lifestyle advice with or without 5α-reductase inhibitor ± α1-blocker/PDE5I
Education + lifestyle advice with or without muscarinic receptor antagonist/beta –3 agonist
Education + lifestyle advice with or without vasopressin analogue

FIG. 145.3 (A) International consensus guideline (2009) algorithm for management of lower urinary tract symptoms *(LUTS):* specialized management. 1, Prostate-specific antigen (PSA) level below 1.5 ng/mL; 2, PSA level above 1.5 ng/mL. (B) Treatment algorithm for male LUTS using medical and/or conservative treatment options. *BOO,* bladder outlet obstruction; *MIST,* minimally invasive surgical treatment; *OAB,* overactive bladder; *PDE5I,* phosphodiesterase type 5 inhibitors; *Rx,* treatment. (A, From Abrams P, Chapple C, Khoury S, et al. Evaluation and treatment of lower urinary tract symptoms in older men. *J Urol* 181[4]:1779–1787, 2009; (B) From Gravas S, Bach T, Drake M, et al. Management of Non-neurogenic male LUTS, incl. benign prostatic obstruction [BPO]. Retrieved from: https://uroweb.org/wp-content/uploads/EAU-Guidelines-Management-of-non-neurogenic-male-LUTS-2016.pdf.)

- Gross hematuria
- UTIs
- Elevated PSA level
- Elevated PVR volume
- Neurologic diseases

The conservative management is based on a WW approach.

Watchful Waiting

WW is based on reassurance and education of the patient, lifestyle interventions, and periodic monitoring of the disease (Oelke et al., 2013).

The rationale behind WW is based on the evidence that a number of patients with LUTS suggestive of BPH are affected by an indolent, nonprogressive disease that does not require active treatment.

The progression of BPH is defined as the deterioration of clinical variables, such as symptoms and PFR, the occurrence of AUR, or the need for surgical treatment. Data from longitudinal community-based studies show that unfavorable outcomes such as AUR and BPH-related surgery are relatively uncommon throughout the natural history of BPH patients, reporting a cumulative incidence of 1% to 2.7% for AUR and 3% for surgery (Jacobsen et al., 1997, 1999; Meigs et al., 1999). In a more recent 15-year longitudinal study, 50% of included patients showed stable symptom scores over the time frame investigated (Fukuta et al., 2012). Similarly, data from the placebo arms of large RCTs assessing the outcomes of medical treatment for BPH showed an incidence of AUR and the need for BPH surgery ranging between 2% and 10% at long-term follow-up (Bruskewitz et al., 1999; McConnell et al., 2003; Roehrborn, 2006).

In an RCT, Wasson et al. (1995) compared the outcomes of 280 patients treated with transurethral resection of the prostate and 276 patients managed with WW. All patients were given simple instructions to avoid coffee, alcohol, and medications potentially worsening their symptoms; surgery was associated with more favorable outcomes in terms of symptom relief, uroflowmetry parameters, and clinical failure rate (defined as the occurrence of any of death, AUR, elevated PVR volume, bladder stones, incontinence, renal failure, and elevated symptom score). However, only 17% of patients experienced treatment failure in the WW group, mainly because of elevated PVR volume or symptom score. Moreover, 24% of WW patients crossed over to surgical treatment during follow-up; those with higher baseline bother score showed a higher risk for crossing over to surgery. In the updated 5-year follow-up study, in the WW group only 1.5% patients experienced AUR and only 1% of patients experienced kidney failure (Flanigan et al., 1998). Of note, patients managed with WW reported reduced urinary symptom scores and a decreased symptom-associated bother at 5-year follow-up.

The impact of a “self-management” approach based on lifestyle and dietary modification, as an integral part of WW, was assessed in RCTs in the past two decades. Specific standards for a self-management approach were defined in a consensus meeting (Brown et al., 2004) and consisted of three small-group sessions of standardized urinary education and lifestyle advice. Brown et al. (2007) evaluated the effectiveness of this approach as a first-line intervention for men with uncomplicated LUTS and mild-to-moderate symptoms in a teaching hospital and a district general hospital in London. A total of 140 men were randomized to either standard care (i.e., simple monitoring of the disease) or a self-management program. The rate of treatment failure and the symptom score at follow-up were significantly lower for the self-management group compared with the control group. Similarly, a multicenter RCT showed that a rigorously structured behavioral program could significantly reduce LUTS severity and decrease symptoms such as nocturia, urgency, and frequency as compared with standard care alone (Yap and Emberton, 2010).

If patients choose WW as the preferred management, they should be followed up yearly to detect any progression in terms of symptoms or the occurrence of complications, which should prompt a more aggressive treatment approach (Abrams et al., 2013; McVary et al., 2011).

Lifestyle and Dietary Modifications

The main components of WW and self-management programs for men with

LUTS are as follows (Yap et al., 2009):

Education and Reassurance

- Discuss the causes of LUTS, including normal prostate and bladder function.
- Discuss the natural history of BPH and LUTS, including the expected future symptoms.
- Reassure the patient that no evidence of detectable PCa has been found.

Fluid Management

- Advise a daily fluid intake of 1500 to 2000 mL (minor adjustments may be made for climate and activity).
- Avoid inadequate or excessive fluid intake on the basis of an FVC.
- Advise fluid restriction when symptoms are most inconvenient (e.g., during long journeys or when out in public).
- Advise evening fluid restriction for nocturia (no fluid for 2 hours before retiring).

Caffeine and Alcohol

- Avoid caffeine by replacing caffeine with alternatives (e.g., decaffeinated or caffeine-free drinks).
- Avoid alcohol in the evening if nocturia is bothersome.
- Replace large-volume alcoholic drinks (e.g., pint of beer) with small-volume alcoholic drinks (e.g., wine or spirits).

Concurrent Medication

- Adjust the time when medication with an effect on the urinary system is taken to reduce LUTS at times of greatest inconvenience (e.g., during long journeys and when out in public).
- Replace antihypertensive diuretics with suitable alternatives with fewer urinary effects (via the patient's general practitioner).

Types of Toileting and Bladder Retraining

- Advise men to double-void (spending extra time on the toilet to try to empty the bladder completely).
- Advise urethral milking for men with postmicturition dribbling.
- Advise bladder retraining. With use of distraction techniques (predetermined mind exercise, perineal pressure, or pelvic floor exercises), aim to increase the minimum time between voids to 3 hours (daytime) and/or the minimum voided volume to between 200

and 400 mL (daytime). The urge to void should be suppressed for 1 minute, then 5 minutes, then 10 minutes, and so on, increasing on a weekly basis. Use FVCs to monitor progress.

Miscellaneous

- Avoid constipation in men with LUTS.

Regarding dietary advice, a recent systematic review of 111 studies assessing the role of diet, fluids, and tobacco on LUTS confirmed a significant association between increased fluid, tea, and caffeine intake with storage symptoms; moreover, a lower alcohol intake was associated with decreased diagnosis of BPH and LUTS (Bradley et al., 2017).

Key Points

- Conservative management is the preferred approach for patients with mild symptoms and without complicating factors.
- WW is based on patient education, lifestyle interventions, and disease monitoring.
- Lifestyle modifications include proper daily fluid intake, tea, caffeine and alcohol avoidance/restriction, and concurrent medication adjustment.
- Patients should be followed up yearly to detect worsening of symptoms or the occurrence of complications.

Medical Therapy

Medical therapy plays a major role in the management of patients with LUTS. **The current drug armamentarium includes α-adrenergic blockers (α_1-blockers), 5ARIs, antimuscarinic drugs, phosphodiesterase type 5 inhibitors (PDE5Is), β_3-agonists, and numerous plant extracts.** Of note, different combinations of medical compounds play a relevant role in the management of LUTS.

Impact and Trends of Medical Therapy Use for Lower Urinary Tract Symptoms

Surgical treatment was the mainstay of treatment for patients with BPH-related

LUTS until the 1990s. Afterward, the use of medical therapies significantly increased (Sarma et al., 2005), along with a reduction of the absolute number of prostatectomies, which decreased from 250,000 in 1987 to 116,000 in 1996 to 88,000 in 2000 and has stabilized since then, according to a survey of the US Medicare database (Wasson et al., 2000). Similar reductions in numbers of transurethral resections of the prostate have been reported in Europe as well.

The preference of patients for medical treatments compared with surgery has been widely demonstrated in several population-based studies (Emberton, 2010; Kaplan and Naslund, 2006; Piercy et al., 1999; Watson et al., 2004).

Beside patient preferences, studies assessing treatment choices among urologists confirmed the prevailing role of medical therapy over surgery (Emberton, 2010). In the PROBE study, including patients from five European countries, 63% of urologists reported prescribing drug therapy to more than 70% of patients, with α_1-blockers being the most frequently prescribed drug (Emberton et al., 2008). Similar data were reported by a US survey investigating treatment preferences of 1087 urologists and 177 primary care physicians, showing that medical therapy was the treatment most commonly suggested by both categories (Seftel et al., 2007).

Clinical Indications

Medical therapy is the first-line treatment for patients bothered by LUTS without imperative indications for surgery, such as the occurrence of AUR, recurrent UTIs, renal insufficiency, bladder stones, and recurrent gross hematuria (McVary et al., 2011; Oelke et al., 2013).

Drug therapy should be tailored to the patient's symptoms (see Fig. 145.3). In a patient with predominantly voiding symptoms, α_1-blockers, 5ARIs and PDE5Is may be all valid treatment options. Several factors, including symptom severity, PV, PVR volume, and patient preferences, should be considered so as to make the proper treatment choice.

Patients suffering from predominant storage symptoms may require therapy with muscarinic receptor antagonists or β_3-agonists. Moreover, different therapeutic strategies should be considered for patients who complain of nocturnal polyuria, defined as nocturnal output exceeding 20% of 24-hour urine output in younger patients or 33% of urine output in men older than 65 years of age as assessed with FVCs (Abrams et al., 2002). In this case, patient education, lifestyle changes, and the optional use of desmopressin have to be considered according to the guidelines for the treatment of nocturia (Sakalis et al., 2017).

The physician should always discuss with the patient the benefits and risks of all available drugs before deciding on a specific treatment.

The outcomes and specific indications of each class of drugs will be discussed throughout this chapter.

Assessment of Response to Medical Treatment: Outcome Measures

The assessment of response to medical treatments is based on the evaluation of quantitative parameters, allowing the physician to objectify the effectiveness of a drug and the possible need to modify the therapy.

The goals of LUTS medical treatment may include relieving symptoms, decreasing BOO, improving bladder emptying, ameliorating DO, reversing renal insufficiency, and preventing disease progression, defined as symptom deterioration and/or the occurrence of complications requiring surgical treatment.

The clinical end points to be evaluated in patients receiving medical treatment for LUTS include symptom severity, BOO, and detrusor function.

Symptoms

Changes in patients' symptoms, as assessed with validated tools such as the AUASI or the IPSS, are considered the gold standard to quantify the impact of therapeutic interventions on LUTS (Barry et al., 1992).

Each treatment can be assessed in terms of the probability and magnitude of symptom relief and the magnitude of bother reduction; the relief on symptom scales can be expressed either as an absolute value or as a percentage change value.

Barry et al. (1995) investigated the clinical significant changes in the AUASI score. Absolute score changes after treatment were compared with five global ratings of symptom relief. **The mean changes in the AUASI score for patients rating their symptoms as markedly, moderately or slightly relieved, unchanged, or worse were −8.8, −5.1, −3.0, −0.7, and +2.7, respectively.** According to these data, **a minimum of a 3-point change in terms of the symptom score appears perceptible to patients.** Of note, because of the nature of tools such as the IPSS and the AUASI, the perceived relief for each increasing point in the total score may differ according to the baseline condition (Barry et al., 1995). Indeed, patients with a higher IPSS, identifying “severe symptoms,” would need a smaller change in their score to perceive a clinically significant relief of symptoms compared with patients who had a lower baseline score suggestive of “mild symptoms.” Therefore, assessment of the percentage score reduction is generally considered more reliable, and has been applied in several clinical trials.

Bladder Outlet Obstruction

The increased resistance in the urine outflow has been associated with profound changes in the bladder ultrastructure and metabolism, with direct implication for bladder function (Levin et al., 2000). For this reason, relief or resolution of BOO is considered an important goal in the treatment of patients with LUTS.

PFSs are the gold standard for the assessment and quantification of BOO; however, as an invasive test, this modality is not suggested for the evaluation of treatment outcomes in clinical practice. Moreover, there is evidence suggesting a lack of correlation between PFS results and treatment efficacy; indeed, parameters such as the bladder contractility index did not prove to be significantly changed after active treatment (Al-Hayek et al., 2004). Nonetheless, the use of invasive urodynamic tests is recommended in clinical trials investigating the effect of a therapeutic intervention in patients with BOO.

As a surrogate for urodynamic parameters, **several studies used uroflowmetry parameters to compare the efficacy of different LUTS treatments;** of those, PFR (Qmax) is considered an indirect measure of BOO (McConnell et al., 1994; Oelke et al., 2007) and is sensitive to treatment modifications. Percentage change rather than absolute change in PFR should be used to evaluate treatment efficacy: relatively small absolute changes in PFR (i.e., 4 to 6 mL/s) correspond to a relatively high percentage change for patients with low baseline PFRs, whereas large absolute changes (i.e., 12 to 17 mL/s) correspond to a relatively low percentage change for patients with a high baseline PFR.

Bladder Emptying

PVR volume is considered an indirect sign of incomplete evacuation and bladder voiding dysfunction, although it does not allow one to differentiate between DUA and BOO (Oelke et al., 2007). While baseline PVR volumes may be predictive of treatment outcomes and complications (Asimakopoulos et al., 2016; Roehrborn 2008), data on post-treatment PVR volumes reported in randomized trials could be misleading; indeed, patients with relevant baseline PVR volumes are usually excluded from these studies, thus undermining the relevance of most clinical trials in the real-life setting. Therefore, there is no standardization in terms of evaluation and meaning of PVR volume changes after LUTS treatment.

Detrusor Overactivity

An urodynamic profile characterized by involuntary detrusor contractions during the filling phase suggests DO, which may be spontaneous or provoked (Abrams, 2003). Morphologic and neurologic alterations of the bladder wall may occur in individuals with BOO, with DO patterns in up to 83% of men with severe BOO (Drake et al., 2017; Thomas et al., 2004). However, longitudinal data failed to demonstrate significant changes in terms of detrusor contractility after active treatment of BOO (Thomas et al., 2005a). Of clinical relevance, urodynamically demonstrated DO is not invariably associated with OAB syndrome (Abrams, 2003). Therefore, although the magnitude of storage symptom relief is useful in the evaluation of treatment efficacy, DO assessment is not considered a standard outcome measure.

Interpreting the Literature: Bias Associated With Trials on Medical Treatment of Lower Urinary Tract Symptoms

Randomized, placebo-controlled, double-blind trials are the best study design to assess the impact of any medical therapy in terms of effectiveness and safety in LUTS/BPH. Caveats still remain across the published literature on this topic.

- There is an important placebo effect in LUTS outcome measures (Nickel, 1998); indeed, both subjective outcomes, such as symptom scale scores, and more objective measures, including uroflowmetry parameters, have been shown to improve from the baseline, even in the placebo arm of RCTs. Therefore, **ideally a 4-week placebo run-in period before initiation of treatment**

should be included in any trial design; this would allow the incorporation of a baseline placebo effect before any comparison is made.

- Sample size is an important issue to be considered in any clinical trial; studies including an insufficient number of patients according to the assessed outcome may not be able to detect a significant difference between treatment groups. Similarly, if the population included is too large, small differences in outcome measurements may be statistically significant, although the real clinical benefit perceived by the patients is not different between treatments. **Therefore, the sample size of clinical trials should be properly determined immediately during the early planning phase of the study.**
- **Inclusion and exclusion criteria of any trial have to be taken into account in the interpretation of the efficacy and tolerability outcomes of a given therapy;** indeed, a specific drug may have a different impact according to patients’ baseline characteristics.
- Data on adverse events (AEs) also should be interpreted with caution. Indeed, AEs can be spontaneously reported by patients, or the patients could be requested to choose from a list of possible AEs; the latter method of assessment could result in a higher rate of reported AEs. Moreover, **most trials are designed to assess the efficacy of a certain drug and could be underpowered to detect a difference in terms of treatment tolerability.**
- **Trial duration has to be taken into account in the interpretation of both the safety and the efficacy of a specific treatment;** indeed, drugs may lose effect over longer periods, and AEs could be detected only after a consistent period of treatment.

Therapy With α_1-Adrenergic Blockers

α_1-Blockers are usually considered as the first-line treatment of LUTS in men

(McVary et al., 2011; Oelke et al., 2013).

Rationale

Adrenergic receptors (ARs) are divided in two macrocategories: α-ARs and β-ARs. Furthermore, a total of nine AR subtypes have been identified: α_{1a}, α_{1b}, α_{1d}, α_{2a}, α_{2b}, α_{2c}, β_1, β_2, β_3 (Fig. 145.4). Each receptor subtype has a distinct molecular structure, pharmacology, and distribution within human tissues; the **α_1-AR subfamily plays a major role in the pathophysiology of LUTS and is the target of α_1-blockers.**

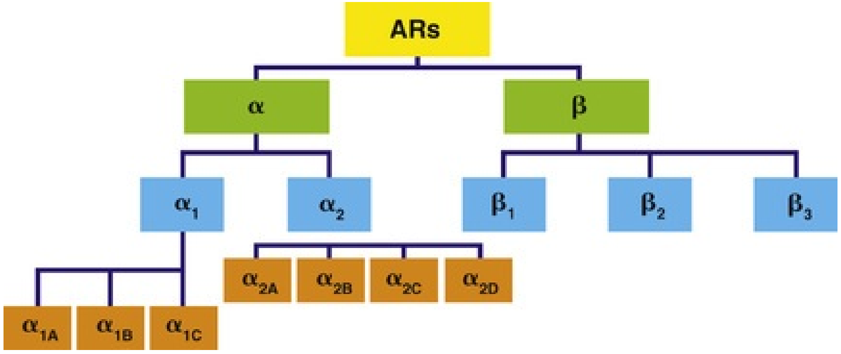

FIG. 145.4 Adrenergic receptor (AR) macrocategories and subtypes.

The distribution of α_1-ARs in human tissues is wide: α_{1a}-ARs are mainly expressed in the liver, followed by the heart and the central nervous system; conversely, α_{1b}-ARs are mainly expressed in blood vessels, spleen, and kidney, and α_{1d}-ARs are highly expressed in the cerebral cortex and the aorta (Price et al., 1994). Overall, smooth muscle contraction is largely mediated by α_1-ARs both in the prostate and urethra (Andersson and Gratzke 2007; Kobayashi et al., 1994; Walden et al., 1999); of the α_1-AR population, the α_{1a} subtype accounts for 70% within the prostate (Andersson, 2002) (Fig. 145.5). Moriyama et al. (1999) analyzed the expression of α_1-AR messenger RNA in BPH and non-BPH prostate tissues, showing that subtypes α_{1a}, α_{1b}, and α_{1d} account for 85%, 14%, and 1% of total expression in BPH prostate tissue compared with 63%, 6%, and 31% in non-BPH prostate tissue, respectively. A similar predominance of α_{1a}-ARs was found at the level of the urethral tissue, including bladder neck and prostatic urethra (Andersson, 2002). Furthermore, α_1-ARs have also been described at the level of the glandular epithelium of the prostate (Walden et al., 1999).

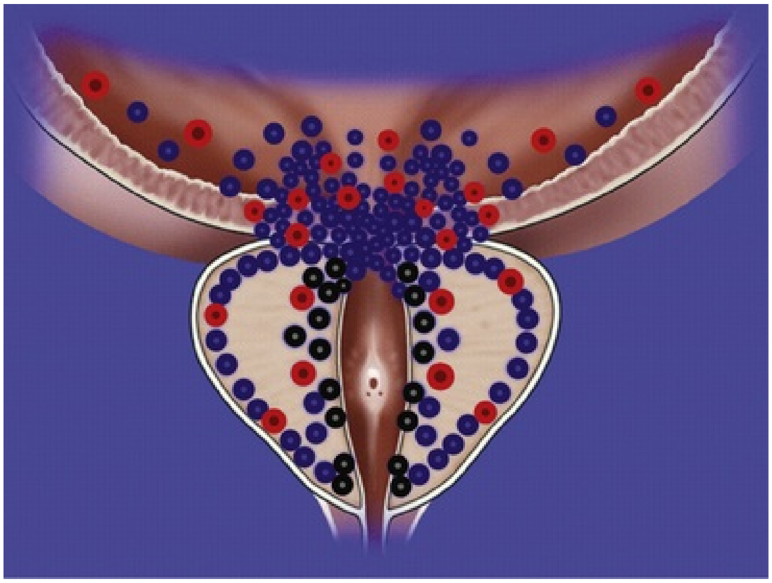

FIG. 145.5 Distribution of α_1-adrenergic receptors at the level of the prostate and bladder neck. The red dots represent α1d receptors, the blue dots represent α1a receptors, and the black dots represent α1b receptors.

Noradrenaline-mediated contraction of the smooth muscle via the binding with α_1-ARs (mainly α_{1a} subtype) at the level of the bladder neck, the proximal urethra, and the prostate is responsible for the dynamic component of BOO in patients with BPH; therefore, **the blockade of α_1-ARs leads to the relaxation of smooth muscle tissue at both sites, with a decrease of the sympathetic baseline muscle tone and the consequent relief of symptoms** (Gup et al., 1989; Lepor et al., 1988). Moreover, α_1-blockers may impact also on the static component of the obstruction; indeed, a suppression of prostate cell proliferation has been observed with α_1-blocker treatment, although it seems to be unrelated to α_1-AR blockade (Chon et al., 1999); whether this effect has a therapeutic significance remains to be established.

Besides the prostate and urethra, α_1-ARs have been detected in the bladder at different sites, including the detrusor muscle, nerve endings, intramural ganglia, urothelium, and interstitial cells (Andersson and Gratzke, 2007). At a subtype level, α_{1d}-ARs are twice as abundant as α_{1a}-ARs in the human detrusor (Malloy et al., 1998). **The effect of α_1-blockers on bladder detrusor function has not**

yet been clarified. Indeed, controversial findings have been reported regarding a possible different pattern of expression of receptor subtypes between obstructed and nonobstructed detrusors (Hampel et al., 2002; Nomiya and Yamaguchi, 2003); likewise, data on the effect of phenylephrine on detrusor contractility are not conclusive (Bouchelouche et al., 2005). A potential beneficial effect of α_1-blockers in treating DO has been supported by the evidence of increased perfusion of the bladder associated with AR blockade; indeed, decreased bladder blood flow is a contributing factor in the pathogenesis of LUTS and OAB syndrome (Andersson et al., 2017).

Chen et al. (2005) showed that mice in which α_{1d}-AR expression had been knocked out had larger bladder capacity and voided volumes compared with controls, thus supporting a facilitating role of α_{1d}-ARs in the voiding reflex. In this context, α_1-ARs may exert inhibitory control on the frequency of voiding through the regulation of afferent processing in the spinal cord (Yoshiyama et al., 2000). Ishihama et al. (2006) showed that α_{1d}-ARs are expressed in the bladder urothelium and that their inhibition affects the voiding reflex through an afferent nerve decrease. Therefore, α_{1d}-ARs seem to play an important role in bladder function regulation both at the level of the urothelium and in afferent nerve pathways. In this context, α_1-blockers with a specific affinity for α_{1d}-ARs have been found to increase bladder volume at the first desire to void and bladder volume at the maximum desire to void, with a reduction of DO (Ishizuka et al., 2013). Further research is needed to draw a final conclusion regarding the role of α_{1d}-ARs in terms of LUTS pathogenesis and the related effect of α_{1d}-AR blockade.

Classification of α_1-Blockers

Two macrocategories of α_1-blockers have been developed over the past three decades, with different affinity for α-ARs and the related effects on the lower urinary tract (Table 145.1).

TABLE 145.1

Classification of α-Adrenergic Blockers and Recommended Doses

CLASS OF α-BLOCKERS	AVAILABLE FORMULATION	RECOMMENDED DAILY DOSE	RECOMMENDED ADMINISTRATION[a]

NONSELECTIVE			
Phenoxybenzamine	10-mg capsule	10 mg bid	No longer indicated for LUTS treatment
SELECTIVE			
Prazosin	0.5[c]-, 1-, 2[d]-, 5[d]-mg capsule	2 mg bid	No longer indicated for LUTS treatment
Indoramin	20-mg capsule	20 mg bid	No longer indicated for LUTS treatment
Terazosin	1[d]-, 2-, 5-, 10[d]-mg capsule	5 or 10 mg qd	Initial dose is 1 mg at bedtime. The dose should be titrated up to 5 or 10 mg.
Doxazosin IR	1-, 2-, 4-mg capsule	2–8 mg qd	Initial dose is 2 mg at bedtime. The dose should be titrated up to 4 or 8 mg.
Doxazosin SR	4-, 8-mg capsule	4 or 8 mg qd	Initial dose is 4 mg after breakfast, eventually increased to 8 mg.
UROSELECTIVE			
Alfuzosin ER[b]	10-mg capsule	10 mg qd	Initial dose is 10 mg with the same meal each day.
Tamsulosin	0.4-, 0.8[d]-mg capsule	0.4–0.8 mg qd	Initial dose is 0.4 mg with the same meal each day.
Silodosin	4-, 8-mg capsule	8 mg qd	Initial dose is 8 mg with the same meal each day.
Naftopidil	25-, 50-mg capsule	25–75 mg/day	Marketed only in Asian countries

[a] As for patient information leaflet.

[b] Alfuzosin is considered a uroselective agent on the basis of the efficacy profile characterized by a preferential effect on the urogenital system.

[c] Marketed only in Europe.

[d] Marketed only in the United States.

αABs, α-Adrenergic blockers; *bid,* twice a day; *ER,* extended release; *qd,* once a day; *IR,* immediate release; *LUTS,* lower urinary tract symptoms; *SR,* sustained release; *tid,* three times a day.

Nonselective α_1-Blockers

Caine et al. (1978) conducted a placebo-controlled double-blind trial to test the efficacy of the novel compound phenoxybenzamine as a symptomatic treatment of BPO; they showed a significant improvement in uroflowmetry parameters and significant relief of patients' symptoms. These results were attributed to the inhibitor effect of phenoxybenzamine on the α-ARs previously isolated at the level of the prostate and the proximal urethra (Caine et al., 1975). **However, because of the nonselectivity of the molecule, blocking both α_1 and α_2 receptor subtypes, serious cardiovascular AEs were observed, and the drug was no longer used to treat LUTS/BPH.**

Selective α_1-Blockers

The discovery of the predominance of the α_1 receptor subtype at the level of the lower urinary tract stimulated the search for molecules with selective affinity for this subtype. **Prazosin was the first selective α_1-AR antagonist investigated for LUTS treatment** (Hedlund et al., 1983); in placebo-controlled studies, prazosin resulted in a significant increase in urinary flow rates (Chapple et al., 1992; Kirby et al., 1987) and was better tolerated than phenoxybenzamine. However, because of its short serum elimination half-life, prazosin requires administration at least twice daily. Afterward, doxazosin and terazosin were developed as selective α_1-AR antagonists with a longer half-life, allowing a more user-friendly once-daily administration (Gillenwater et al., 1995; Lepor et al., 1992), although both drugs were associated with significant treatment-emergent AEs caused by smooth muscle relaxation at the level of the vascular district.

Therefore, to maintain efficacy and reduce the incidence of AEs, α_1-blockers selective for the prostatic and urethral tissue were then developed (Andersson, 1998); **tamsulosin, alfuzosin, silodosin, and naftopidil are defined as uroselective drugs and have a higher affinity for the α_{1a} and α_{1d} receptor subtypes than for the α_{1b} subtype.**

Review of the Literature on Currently Approved α_1-Blockers for the Treatment of Lower Urinary Tract Symptoms

Several RCTs investigated the efficacy and tolerability of α_1-blockers for the

treatment of LUTS; pooled analyses have provided level 1a evidence for each compound.

The effect and tolerance of α_1-blockers are dose dependent; therefore, randomized trials have been conducted with different designs so as to provide data on dose-dependent efficacy and tolerability (titration to fixed-dose design) and data on the threshold dose for the maximal achievable response in clinical practice (titration to response or to maximal dose design).

The trials investigating both the safety and efficacy of the nonselective α_1-blockers phenoxybenzamine (Abrams et al., 1982; Caine et al., 1978), prazosin (Chapple et al., 1992; Hedlund et al., 1983; Kirby et al., 1987), and indoramin (Chow et al., 1990; Iacovou and Dunn, 1987) are not discussed in this chapter because all of the aforementioned compounds are no longer used for the medical treatment of BPH.

The results of the most significant RCTs and comparative studies on terazosin, doxazosin, extended-release (ER) alfuzosin, tamsulosin, silodosin, and naftopidil are summarized and discussed next.

Terazosin

Several RCTs have demonstrated the efficacy of terazosin in patients with LUTS related to BPE (Table 145.2).

TABLE 145.2

Randomized Placebo-Controlled Trials Evaluating the Efficacy and Tolerability of Terazosin

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (MEAN CHANGE FROM BASELINE [SD]; PERCENTAGE CHANGE [P[a]])	
Lepor et al., 1992	Terazosin 2 mg Terazosin 5 mg	*N* = 285 50–75 years of age with symptomatic	12 weeks	Boyarsky total 2 mg: –3.3 (0.4); –33 (0.09) 5 mg: –3.6 (0.4);	

	Terazosin 10 mg Placebo	BPH (score ≥1 point for at least two obstructive symptoms on the Boyarsky symptom scale)		–33 (0.042) 10 mg: –4.5 (0.5); –45 (<0.001) placebo: –2.3 (0.5); –24	
Brawer et al., 1993	Terazosin titrated up to 10 mg Placebo	*N* = 160 >45 years of age with symptomatic BPH (score ≥1 point for at least two obstructive symptoms on the Boyarsky symptom scale)	24 weeks	Boyarsky total 10 mg: –4.6 (0.4); –42 (<0.05) Placebo: –1.1 (0.4); –10	
Elhilali et	Terazosin	*N* = 164	24 weeks	10 mg: –3.4; –31	

al., 1996	titrated up to 10 mg Placebo	50–80 years of age with symptomatic BPH (score ≥1 point on at least two obstructive symptoms on the Boyarsky symptom scale)		(0.05) Placebo: –1.6; –15	
Lepor et al., 1996	Terazosin titrated up to 10 mg Placebo	*N* = 610 50–75 years of age with symptomatic BPH (IPSS ≥8)	52 weeks	IPSS total 10 mg: –6.1; -38 (<0.001) Placebo: –2.6; -16	
Roehrborn et al., 1996	Terazosin titrated up to 10 mg Placebo	*N* = 2084 ≥55 years of age with symptomatic BPH (IPSS ≥13)	52 weeks	IPSS total 10 mg: –7.6 (0.21); –38 (<0.001) Placebo: –3.7 (0.22); –18	

[a] Compared with placebo.

[b] The three most common adverse events are reported if available.

[c] Estimates are significantly different as compared with placebo.

BPH, Benign prostatic hyperplasia; *IPSS,* International Prostatic Symptom Score; *SD,* standard deviation.

Lepor et al. (1992) published the first phase III multicenter trial, with 285 patients with LUTS suggestive of BOO randomized to receive placebo or 2 mg, 5 mg, or 10 mg terazosin once daily for a 12-week treatment period. **The results showed a 22.4% reduction in symptom score (Boyarsky symptom scale) in favor of the treatment group. Moreover, patients treated with terazosin had a significant increase in PFRs and mean urinary flow rates. Both effects were dose dependent, with better results with 10 mg terazosin. Overall, AEs were minor and reversible in all four terazosin-treated groups.** In this context, higher but not statistically significant incidences of asthenia, flu syndrome, and dizziness were observed for the terazosin-treated groups compared with the placebo group. Conversely, a significantly greater incidence of postural hypotension was reported in the 5-mg terazosin group compared with the placebo group. The incidence of syncope for all terazosin-treated patients was less than 0.5%.

The two longest and largest trials (including 68% of patients enrolled in all published RCTs assessing the effect of terazosin vs. placebo) provided significant findings on the effect and safety of terazosin. In the four-arm study of Lepor et al. (1996), 305 men randomized to receive terazosin were compared with 305 men randomized to receive placebo. Patients were included if they had a PFR of less than 15 mL but more than 4 mL and a PVR volume less than 300 mL. A terazosin dose titration was applied, with 80% of patients receiving the maximum dose of 10 mg by the end of the study. AUASI scores significantly decreased by 6.1 points in the terazosin group at the 1-year assessment. Similarly, the mean increase in PFR was significant after 12 months for terazosin compared with placebo (2.7 vs. 1.4 mL/s). **Dizziness and asthenia were the most commonly reported AEs in the terazosin group (26% and 14%, respectively)**; postural hypotension was reported in 8% of patients in the terazosin group versus 1% of patients in the placebo group ($P < 0.001$).

Roehrborn et al. (1996) reported the results of the 1-year multicenter Hytrin Community Assessment Trial (HYCAT), which enrolled 2084 men with an

AUASI score of 13 or greater and a PFR of less than 15 mL/s. Patients were randomized to receive placebo or terazosin; the dose was titrated from 1 mg to 5 mg or 10 mg according to the clinical response. **The symptom score decreased by 37.8% in the terazosin group and by 18.4% in the placebo group (*P* < 0.001)** (Fig. 145.6); **similarly treatment with terazosin significantly improved urinary flow parameters. Of note, 19.7% of patients discontinued use of terazosin because of AEs.** Dizziness was the most frequent AE (11.7% of cases).

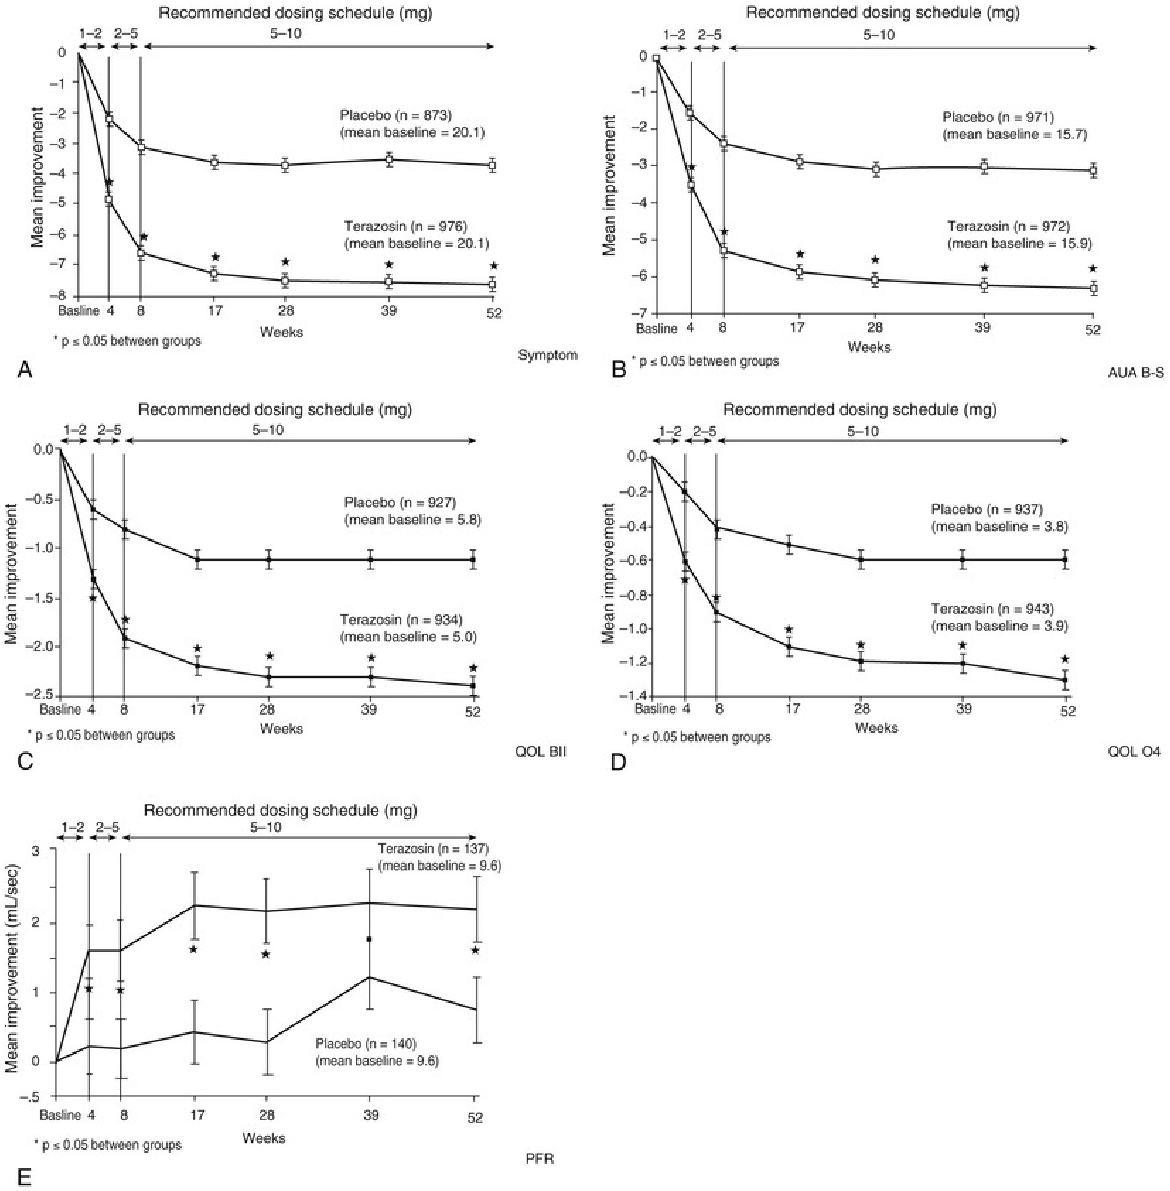

FIG. 145.6 Time course of reductions in (A) AUA Symptom Score, (B) AUA Bothersome Score, (C) BPH Impact Index *(BII)*, (D) quality-of-life

score (QoL), and (E) peak urinary flow rate for placebo and terazosin treatment groups. A lowering of the score represents clinical improvement. (From: Roehrborn CG, Oesterling JE, Auerbach S, et al. The Hytrin Community Assessment Trial study: a one-year study of terazosin versus placebo in the treatment of men with symptomatic benign prostatic hyperplasia. HYCAT Investigator Group. *Urology*. 47[2]:159–168, 1996. Figure 2, p. 163.)

Evidence from basic science has shown that terazosin induces prostate epithelial and stromal apoptosis (Chon et al., 1999). This effect is related to the quinazoline structure of the drug rather than the antagonist effect on α-ARs; however, **terazosin was not shown to reduce PV when compared with placebo** (Lepor et al., 1996).

Regarding the effect of terazosin on BOO, as assessed with urodynamic tests, a recent meta-analysis including both randomized and observational trials showed a decrease of 6.69 (95% CI, –11.35 to –2.04) in the BOO index (BOOI) associated with terazosin treatment (Fusco et al. 2016), suggesting a clinically significant impact of terazosin on BOO.

Wilt et al. (2002a) systematically reviewed the findings of 10 randomized trials on terazosin versus placebo. The analyses confirmed the efficacy of terazosin in terms of symptom relief and urinary flow rate increase, with some evidence in favor of a 10-mg dose; overall, AEs were associated with a twofold to fourfold increase in the rate of treatment discontinuation. In this context, terazosin **dose titration is recommended to minimize the risk for first-dose hypotension and syncope. Patients should be counseled to start treatment with 1 mg terazosin taken at bedtime, further increasing up to 5 or 10 mg** (see Table 145.1). Kirby (1998) examined mean blood pressure changes according to whether patients were normotensive or hypertensive at baseline. Overall, in normotensive men, small clinically insignificant decreases in blood pressure were noted; untreated hypertensive men had larger and clinically significant decreases in blood pressure; medically controlled hypertensive patients did not show a significant change in blood pressure, whereas poorly controlled individuals showed significantly lowered blood pressure after terazosin treatment.

Doxazosin

Multicenter, randomized, placebo-controlled trials assessed the efficacy and tolerability of doxazosin in men with LUTS/BPH (Table 145.3). In a 16-week, double-blind, multicenter trial, 100 patients were randomized to receive doxazosin or placebo (Fawzy et al., 1995). All patients had symptomatic BPH with an AUASI score of 10 or greater, PFR of 5 to 15 mL/s, and PVR volume of 125 to 500 mL; dose titration was applied to 2, 4, or 8 mg once daily (88% of patients reached the 8-mg dose). **The symptom score decreased significantly by 39% in the treatment group compared with 17% in the placebo group ($P < 0.001$); similarly, PFR increased by a mean of 2.9 mL/s with doxazosin compared with 0.7 mL/s with placebo. All patients were normotensive at enrollment, and hypotension was reported by 8% of patients.** The incidences of dizziness, fatigue, headache, somnolence, and nausea were 20%, 8%, 8%, 6%, and 8%, respectively. Withdrawal because of treatment-emergent AEs occurred in 14% of patients in the doxazosin group and in 2.1% of patients in the placebo group. Gillenwater et al. (1995) reported data from a larger multicenter RCT including 248 hypertensive patients randomized to 16-week therapy with doxazosin or placebo. Efficacy and safety were investigated for 2, 4, 8, and 12 mg doxazosin doses, with titration to a fixed-dose approach. **The results showed a significant reduction of symptom severity only for doxazosin at doses of 4 and 8 mg over placebo, although the small number of patients in each dosing group may be responsible for the lack of significance compared with placebo for the other doses.** The average PFR increased from 2.3 to 3.6 mL/s in the 4-, 8-, and 12-mg doxazosin groups, compared with 0.1 mL/s in the placebo group ($P < 0.01$); this increase was significant, even after only 1 week of therapy. The overall treatment-related incidences of dizziness and fatigue were 15% and 10%, respectively. **Standing and sitting blood pressure significantly decreased for the 4-, 8-, and 12-mg doxazosi**n **groups compared with placebo, with a maximum average decrease in systolic blood pressure of 17.4 mm Hg in the standing position. These data confirmed the significant impact of doxazosin on blood pressure, at least in hypertensive men.** Other trials showed lower overall mean decrease in sitting and standing blood pressure for normotensive men treated with doxazosin (Fawzy et al., 1995; Kirby et al., 1998; Lepor et al., 1997). In a pooled analysis of 10 placebo-controlled trials with doxazosin, MacDonald et al. (2004) showed that the relative risk for postural hypotension with doxazosin was 2.72 (95% CI, 1.21 to 6.15) compared with placebo, considering both hypertensive and normotensive patients. The overall incidences of dizziness, asthenia, and postural hypotension were 11%, 6%, and 2% with doxazosin compared with 7%, 3%, and less than 1% with placebo, respectively.

TABLE 145.3

Randomized Placebo-Controlled Trials Evaluating the Efficacy and Tolerability of Doxazosin

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (MEAN INCREASE FROM BASELINE [SD]; PERCENTAGE CHANGE [P[a]])
Chapple et al., 1994	Doxazosin 4 mg Placebo	*N* = 135 Symptomatic patients with urodynamically confirmed BOO (PFR <15 mL/s)	14 weeks	NR
Fawzy et al., 1995	Doxazosin titrated 1 to 8 mg Placebo	*N* = 100 >45 years of age, with symptomatic BPH (IPSS ≥10; PFR 5–15 mL/s)	17 weeks	IPSS total 1–8 mg: –5.7; –39 (<0.001) Placebo: –2.5; –17
Gillenwater et al., 1995	Doxazosin 2 mg Doxazosin 4 mg Doxazosin 8 mg Doxazosin 12 mg	*N* = 248 ≥45 years of age with mild to moderate HT and symptomatic BPH (PFR 5–15 mL/s; PVR	16 weeks	Modified Boyarsky total 2 mg: –2.8; –10 (NS) 4 mg: –5.0; –17 (<0.01) 8 mg: –4.2; –14 (<0.05)

	Placebo	<200 mL; daytime voids ≥4, nocturia ≥2)		12 mg: –3.6; –12 (NS) Placebo: –2.5; –9
Andersen et al., 2000	Doxazosin titrated from 1 to 8 mg Doxazosin GITS 4–8 mg Placebo	*N* = 795 50–80 years of age with symptomatic BPH (IPSS ≥12; PFR 5–15 mL/s)	17 weeks	IPSS total 1–8 mg: –8.4 (0.3); –47 (<0.001) GITS: –8.0 (0.3); –45 (<0.001) Placebo –6.0 (0.4); –33
Kirby et al., 2003	Doxazosin titrated from 1 to 8 mg Placebo	*N* = 545 50–80 years of age with symptomatic BPH (IPSS ≥12; PFR 5–15 mL/s)	54 weeks	IPSS total 1–8 mg: –8.3 (0.4); –49 (<0.05) Placebo: –5.7 (0.4); –33
McConnell et al., 2003	Doxazosin titrated from 1 to 8 mg Placebo	*N* = 1,493 ≥50 years of age with symptomatic BPH (IPSS ≥8; PFR 4–15 mL/s)	Mean follow-up 234 weeks	IPSS total: 1–8 mg: –6.6; –39 (<0.001) Placebo –4.9; –29

[a] Compared with placebo.

[b] The three most common adverse events are reported if available.

[c] Estimates are significantly different as compared with placebo.

AEs, Adverse events; *BPH,* benign prostatic hyperplasia; *GITS,* gastrointestinal therapeutic system; *IPSS,* International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *PFR,* peak flow rate; *PVR,* postvoid residual volume; *SD,* standard deviation.

Both the 1-year Prospective European Doxazosin and Combination Therapy (PREDICT) trial (Kirby et al., 2003) and the 4-year MTOPS trial (McConnell et al., 2003) provided evidence of the maintenance of symptom score decrease and PFR increase with doxazosin therapy at long term-follow up. **Findings from the MTOPS trial showed that doxazosin alone reduced the risk for clinical progression of BPH by 39% as compared with placebo ($P < 0.001$)** (McConnell et al., 2003).

In a recent meta-analysis assessing the effect of α_1-blocker treatment on urodynamic parameters, a significant effect of doxazosin on BOO was observed, with a decrease of 19.4 points of the BOOI (Fusco et al., 2016).

A gastrointestinal therapeutic system (GITS) sustained-release (SR) formulation of doxazosin was developed as a controlled-release formulation to enhance the pharmacologic profile of the drug (Chung et al., 1999); the GITS formulation had a lower maximum plasma concentration of doxazosin and a minimum concentration sustained for a longer period compared with the standard formulation (Chung et al., 1999). Two randomized, double-blind, parallel-group multicenter studies compared the efficacy of GITS therapy (starting dose of 4 mg, then uptitrated to 8 mg to reach clinical efficacy) versus standard doxazosin (from 1 mg up to 8 mg) (Andersen et al., 2000; Gratzke and Kirby 2000); the combined analysis of both trials confirmed the overall comparable efficacy of both formulations (Kirby et al., 2001). Of all patients randomized to receive GITS therapy, 42.6% continued to use the 4-mg formulation; moreover, AE incidence was lower in the GITS group compared with the standard doxazosin group (16.1% vs. 25.3%, respectively). Similarly, treatment withdrawal caused by AEs was lower in the GITS group (3.3% vs. 4.8%, respectively). Overall, the **doxazosin GITS therapy showed a pattern of earlier onset of symptom relief and increase in flow rates compared with the doxazosin standard formulation; this finding was related to the possibility to start the therapy at a higher dose (4 mg), with no need for dose titration for the SR formulation** (Kirby et al., 2001)**. Doxazosin SR is recommended at the initial dose of 4 mg taken at breakfast** (see Table 145.1).

As for terazosin, the quinazoline structure of doxazosin was associated with cell apoptosis in vitro. The mean apoptotic index in the epithelial and stromal prostate components was shown to increase from 1.9% and 1.0% to 6% and 12%, respectively, after 3 months of doxazosin treatment (Kyprianou et al., 1998). Ilio et al. (2001) suggested that this effect might be caused by the autocrine production of transforming growth factor β_1 stimulated by doxazosin. However, as for terazosin, **no significant changes in PV have been reported after treatment with doxazosin compared with placebo** (McConnell et al., 2003).

Alfuzosin

Alfuzosin was launched as a uroselective α_1-blocker. Although the compound does not have in vitro selectivity for any of the α_1-AR subtypes, alfuzosin shows clinical uroselectivity, which is related to a preferential effect of the drug on the urogenital system. Indeed, in isolated human tissues, alfuzosin showed a high selectivity ratio toward prostate tissue over vascular tissue (Mottet et al., 2003). Moreover, alfuzosin has poor diffusion in the central nervous system (CNS) (Rouquier et al., 1994). **This pharmacokinetic profile is reflected in a high efficacy for relieving LUTS, along with a lower rate of cardiovascular AEs (postural hypotension, syncope, vertigo, and dizziness) or CNS AEs (somnolence, asthenia)** (Table 145.4).

TABLE 145.4

Randomized Placebo-Controlled Trials Evaluating the Efficacy and Tolerability of Alfuzosin

	SYMPTOMS (MEAN INCREASE

	DRUG	PATIENTS	LENGTH OF TREATMENT	FROM BASELINE [SD]; PERCENTAGE CHANGE [P[a]])
Jardin et al., 1991	Alfuzosin IR 7.5–10 mg Placebo	*N* = 518 45–81 years of age with symptomatic BPH (Boyarsky score ≥6)	26 weeks	Boyarsky total 7.5–10 mg: –4; –42 (0.0004) Placebo: –3; –32
Martorana et al., 1997	Alfuzosin IR 7.5 mg Placebo	*N* = 94 47.80 years of age with symptomatic BPH (Boyarsky score ≥6; PFR 5–12 mL/s)	4 weeks	Boyarsky total 7.5 mg: –2–7; –25 (NS) Placebo: –2.5; –24
Buzelin et al., 1997a	Alfuzosin SR 10 mg Placebo	*N* = 390 >45 years of age with symptomatic BPH (daytime micturitions ≥8 or nocturia ≥2; PFR 5–15 mL/s; PVR <150 mL)	12 weeks	IPSS total 10 mg: –5.0; –31 (0.007) Placebo: –3.4; –18
van Kerrebroeck et al., 2000	Alfuzosin qd 10 mg Alfuzosin 7.5 mg	*N* = 447 >50 years of age with symptomatic	12 weeks	IPSS total 10 mg: –6.9; –40 (0.002) 7.5 mg: –6.4; –

	Placebo	BPH (IPSS ≥13; PFR 5–12 mL/s; PVR >350 mL)		38 (0.02) Placebo –4.9; –28	
Roehrborn et al., 2001	Alfuzosin qd 10 mg Alfuzosin qd 15 mg Placebo	*N* = 536 ≥50 years of age with symptomatic BPH (IPSS ≥13; PFR 5–12 mL/s; PVR >350 mL; QoL score ≥3)	12 weeks	IPSS total 10 mg: –3.6 (4.8); –20 (0.001) 15 mg: –3.4 (5.7); –19 (0.004) Placebo –1.6 (5.8); –9	

[a] Compared with placebo.

[b] The three most common adverse events are reported if available.

AEs, Adverse events; *BPH,* benign prostatic hyperplasia; *IR,* intermediate release; *IPSS,* International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *PFR,* peak flow rate; *PVR,* postvoid residual volume; *qd,* once a day; *SD,* standard deviation; *SR,* sustained release; *tid,* three times a day.

Alfuzosin was initially tested in a 2.5-mg immediate-release (IR) formulation administered three times daily; Jardin et al. (1991) assessed the efficacy of IR alfuzosin in an RCT with 518 symptomatic men with BPH, showing significant relief of both storage and voiding symptoms (formerly defined obstructive and irritative symptoms) in the treatment group. The overall incidence of AEs was comparable between groups. Afterward, a novel SR formulation of 5 mg, allowing administration twice daily, was tested in a placebo-controlled trial (Buzelin et al., 1997a). After 12 weeks, there was a reduction of 31% versus 18% in the IPSS in the alfuzosin group and the placebo group, respectively ($P = 0.007$); moreover, patients treated with SR alfuzosin showed a mean increase in PFR of 2.4 mL/s compared with 1.1 mL/s in the placebo group. As for the IR formulation, the rate of treatment-emergent AEs was low and comparable with that for placebo, with rates of vascular-related events of 3.1% and 3.6% in the alfuzosin group and the placebo group, respectively.

To improve the convenience of dosing, a 10-mg once-daily formulation was developed; van Kerrebroeck et al. (2000) compared the efficacy and safety of once-daily alfuzosin with IR alfuzosin and placebo in 447 patients. Both alfuzosin groups showed a comparable significant decrease in terms of IPSS compared with placebo (10 mg once daily, –6.9; 2.5 mg three times daily, –6.4; placebo, –4.9; $P = 0.005$). Similarly, the mean increase in PFR was comparable between alfuzosin-treated groups and significantly superior to that resulting from use of placebo. The incidence of vasodilatory AEs was lower with the once-daily formulation compared with the IR formulation (6.3% vs. 9.4%, respectively), and no first-day effect on blood pressure was reported with the 10-mg dosing in both normotensive and hypertensive patients. The clinical benefits of alfuzosin once daily was maintained in the 9-month open-label extension. These results were further confirmed in the ALFUS trial, which assessed the efficacy of 10 mg once-daily alfuzosin versus placebo in a double-blind fashion (Roehrborn, 2001).

Overall, these findings showed 10 mg once-daily alfuzosin is an effective and safe compound with no need for dose titration. Alfuzosin should be taken after the same meal each day (see Table 145.1).

In a meta-analysis comparing the results of eight RCTs (see Table 145.4), alfuzosin was highly effective in relieving symptoms and improving uroflowmetry parameters, with good efficacy maintained up to 3 years of treatment (MacDonald and Wilt, 2005); dizziness was the most frequently reported AE, ranging in incidence from 1.7% to 11.8%, whereas other vasodilatory effects, including hypotension, syncope, and somnolence, occurred in less than 2% of participants. Moreover, in a systematic review of studies assessing urodynamic findings, treatment with alfuzosin was associated with a mean BOOI change of –14.88 (95% CI, –26.68 to –3.08) (Fusco et al., 2016).

Tamsulosin

Tamsulosin is a uroselective α_1-blocker with higher affinity for the α_{1a} and α_{1d} receptor subtypes (Noble et al., 1997). In vitro pharmacokinetic studies showed that the selectivity of tamsulosin for the α_{1d} subtype is marginally greater than that for the α_{1a} subtype, but 10-fold greater for α_{1a} than for α_{1b}. In a rat model of BPH, Kojima et al. (2011) demonstrated that the administration of tamsulosin led to a dose-dependent increased expression of α_{1a} and α_{1d} receptors in prostatic tissue, thus confirming the uroselectivity of the drug. This profile confers tamsulosin with excellent efficacy along with good tolerability.

The efficacy and safety of tamsulosin were investigated in five RCTs (Table 145.5) (Abrams et al., 1995, 1997; Chapple et al., 1996; Lepor 1998a; Narayan and Tewari, 1998).

TABLE 145.5

Randomized Placebo-Controlled Trials Evaluating the Efficacy and Tolerability of Tamsulosin

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (MEAN INCREASE FROM BASELINE [SE]; PERCENTAGE CHANGE [P[a]])
Abrams et al., 1995	Tamsulosin 0.4 mg Placebo	*N* = 296 ≥45 years of age with symptomatic BPH (Boyarsky score >6; PFR 4–12 mL/s)	14 weeks	Boyarsky total 0.4 mg: –2.4 (0.2); –36 (0.002) Placebo: –2.2 (0.3); –24
Abrams et al.,	Tamsulosin 0.2 mg	*N* = 126 50–85 years	7 weeks	Boyarsky total 0.2 mg: –3.4; –

1997	Tamsulosin 0.4 mg Tamsulosin 0.6 mg Placebo	of age with symptomatic BPH (PFR <15 mL/s)		20 (NS) 0.4 mg: –4.1; –29 (NS) 0.6 mg: –4.4; –28 (NS) Placebo: –2,9; –18	
Chapple et al., 1996	Tamsulosin 0.4 mg Placebo	*N* = 575 ≥45 years of age with symptomatic BPH (Boyarsky score >6; PFR 4–12 mL/s)	14 weeks	Boyarsky total 0.4 mg: –3.3 (3.1); –35 (0.002) Placebo: –2.4 (3.2); –26	
Lepor, 1998a	Tamsulosin 0.4 mg Tamsulosin 0.8 mg Placebo	*N* = 756 ≥45 years of age with symptomatic BPH (IPSS ≥13; PFR 4–15 mL/s)	17 weeks	IPSS total 0.4 mg: –9.3 (6.3); –41 (<0.001) 0.8 mg: –9.6 (6.2); –48 (<0.001) Placebo: –5.5 (6.3); –28	
Narayan and	Tamsulosin 0.4 mg	*N* = 735 ≥45 years of	17 weeks	IPSS total 0.4 mg: –5.1	

Tewari, 1998	Tamsulosin 0.8 mg Placebo	age with symptomatic BPH		(6.4); –27 (0.01) –5.8 (6.4); –30 (0.01) –3.6 (5.7); –19	

[a] Compared with placebo.

[b] The three most common adverse events are reported if available.

[c] Estimates are significantly different as compared with placebo.

AEs, adverse events; *BPH,* benign prostatic hyperplasia; *IPSS,* International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *PFR,* peak flow rate; *SE,* standard error.

In a phase III multicenter trial, 756 patients with BPH were randomized to receive either tamsulosin (0.4 vs. 0.8 mg/day) or placebo for 13 weeks (Lepor 1998a); the mean change in the AUASI score was –8.3 in the 0.4-mg group versus –5.5 in the placebo group ($P<0.001$), and the tamsulosin dose of 0.8 mg was associated with a mean decrease of 9.6 points, which was significantly greater than with both placebo and the 0.4-mg dose ($P < 0.02$) (Fig. 145.7). Moreover, both treatment groups showed a significant higher mean increase of the PFR than the placebo group (0.4 mg, 1.75 mL/s; 0.8 mg, 1.78 mL/s; placebo, 0.5 mL/s). Rhinitis, dizziness, and abnormal ejaculation were reported in 5%, 3%, and 6% of patients, respectively, with the tamsulosin dose of 0.4 mg, and in 6%, 9%, and 18% of patients, respectively, with the tamsulosin dose of 0.8 mg. Of clinical relevance, **PFR increased within 4 to 8 hours after a single 0.4-mg dose, and symptom relief was evident after 1 week of treatment.** Overall, AE incidence was comparable after treatment with the 0.4-mg dose and placebo, but was greater for the 0.8-mg dose. Mean changes in systolic and diastolic blood pressure did not differ between placebo and tamsulosin in both hypertensive and normotensive patients. The open-label extension of the same trial confirmed these results in terms of efficacy and safety after 40 weeks of treatment (Lepor, 1998b).

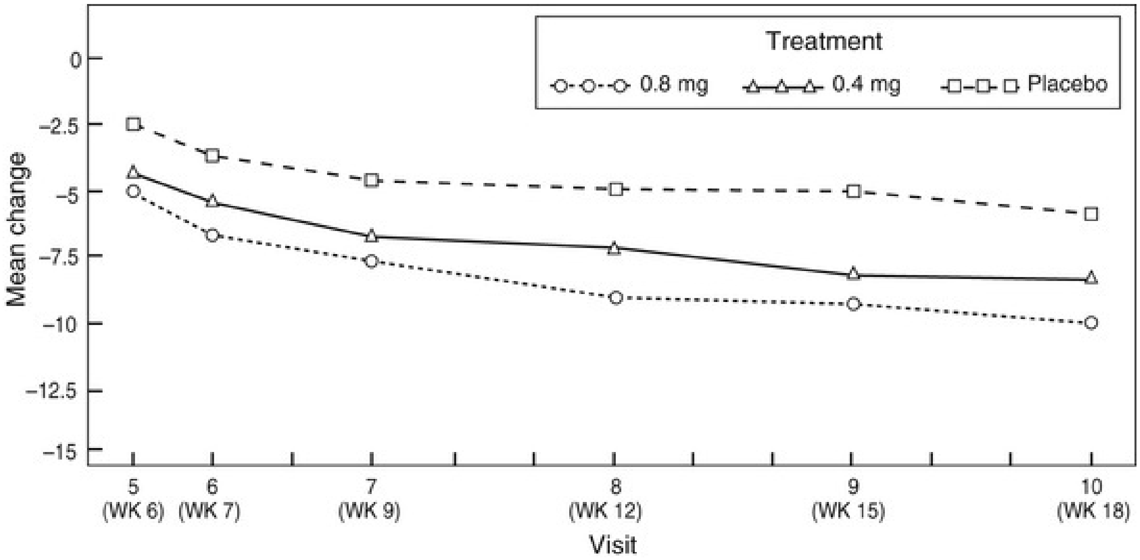

FIG. 145.7 Mean change from the baseline in the total American Urological Association Symptom Score by visit. Changes from the baseline were apparent for all three treatment groups as early as 1 week after the initiation of double-blind therapy. Near-maximal responses were obtained by visit 8, approximately 8 weeks after the initiation of double-blind therapy. (From: Lepor H. Phase III multicenter placebo-controlled study of tamsulosin in benign prostatic hyperplasia. Tamsulosin Investigator Group. *Urology* 51[6]:892–900, 1998a. Figure 1A, p. 896.)

Narayan and Tewari (1998) reported similar results investigating the effect of 0.4 and 0.8 mg tamsulosin versus placebo in 735 patients in a double-blind fashion. After 13 weeks of therapy, both treatment groups showed a significant reduction of symptom scores and significant increase of urinary flow rates compared with the placebo group; the results were comparable between active doses, although the study lacked statistical power to detect a significant difference between the two treatment groups. The incidences of asthenia, dizziness, rhinitis, and abnormal ejaculation were 2%, 5%, 3%, and 11%, respectively, after treatment with 0.4 mg tamsulosin, with a higher incidence of rhinitis and abnormal ejaculation in the 0.8-mg group. No significant changes in systolic blood pressure were reported.

Wilt et al. performed a meta-analysis of RCTs assessing the efficacy of tamsulosin versus placebo and showed a percentage reduction in symptom score ranging from 20% to 48% and a mean change in PFR ranging from 1.2 to 4 mL/s after tamsulosin therapy (Wilt et al., 2003). Symptomatic relief **was slightly greater with 0.8 mg tamsulosin compared with 0.4 mg tamsulosin; however, notwithstanding that tamsulosin was generally well tolerated, the rates of AEs and treatment withdrawal were dose dependent, and therefore 0.4 mg tamsulosin emerged as the formulation of choice for LUTS treatment. Tamsulosin is recommended at the dose of 0.4 mg taken after the same meal each day** (see Table 145.1).

Overall, tamsulosin has been shown to relieve both voiding and storage symptoms. In a prospective trial involving 160 patients with nocturia, tamsulosin significantly improved QoL by reducing the nocturnal frequency, as assessed with FVCs (Yoshida et al., 2010). Moreover, a recent study assessing the effect of tamsulosin on specific symptoms by a cluster analysis showed that nocturia was significantly reduced by tamsulosin, with the strongest impact on QoL improvement along with weak stream (Aikawa et al., 2015). These results are supported by preclinical findings showing that the administration of tamsulosin is associated with an increased bladder blood flow and the amelioration of bladder overactivity in a rat model (Okutsu et al., 2011).

Finally, in a pooled analysis including five studies assessing the urodynamic effects of tamsulosin in patients with BOO, the compound showed a significant mean change of –14.27 points (95% CI, –23.30 to –5.23 points) in the BOOI (Fusco et al., 2016).

Silodosin

As a uroselective α_1-blocker, silodosin has demonstrated the highest selectivity for the α_{1a}-AR subtype, with 583-fold and 56-fold higher binding affinity compared with the α_{1b} and α_{1d} subtypes, respectively (Moriyama et al., 1997; Shibata et al., 1995).

Four prospective RCTs were conducted to evaluate the superiority of silodosin over placebo and the noninferiority of silodosin compared with tamsulosin in men with LUTS/BPH (inclusion criteria of moderate-to severe LUTS, PV greater than 20 mL, PFR less than 15 mL/s) (Table 145.6) (Chapple et al., 2011; Kawabe et al., 2006; Marks et al., 2009a). The pooled analysis of the American registration trials showed a change of IPSS of –6.4 for patients randomized to receive 8 mg silodosin compared with –3.5 for those randomized to receive placebo after 12 weeks of treatment ($P < 0.0001$) (Marks et al., 2009a). PFR increased by 2.6 mL/s in the silodosin group and by 1.5 mL/s in the placebo group ($P < 0.0001$). The drug showed a rapid onset time, with significant symptom relief as early as 3 to 4 days after treatment along with a PFR increase greater than with placebo 2 to 6 hours after the initial dose. The most commonly reported AE was anejaculation (28.1%), although only 2.8% of patients discontinued use of silodosin because of this symptom. The three-arm European registration trial (Chapple et al., 2011) confirmed the good efficacy of 8 mg silodosin as compared with placebo and the noninferiority compared with 0.4 mg tamsulosin (Fig. 145.8). Moreover, in the open-label extension studies of both trials, the efficacy and safety of the drug were investigated up to 9 months (Marks et al., 2009b; Osman et al., 2015); the results showed further relief of both storage and voiding symptoms at the long-term assessment; again, anejaculation was the most commonly reported AE, followed by dizziness, whereas orthostatic hypotension was rarely observed. **Silodosin is recommended at the daily dose of 8 mg taken with a meal** (see Table 145.1).

TABLE 145.6

Randomized Placebo-Controlled Trials Evaluating the Efficacy and Tolerability of Silodosin

	DRUG	PATIENTS	LENGTH OF TREATMENTS	SYMPTOMS (MEAN INCREASE FROM BASELINE [SD]; PERCENTAGE CHANGE [P[a]])	

Kawabe et al., 2006	Silodosin 8 mg Placebo	*N* = 126 ≥50 years of age with symptomatic BPH (IPSS ≥8, QoL score ≥3, PV ≥20 mL, PFR <15 mL/s, PVR <100 mL)	12 weeks	IPSS total 8 mg: –8.3 (6.4); (<0.006) Placebo: –5.3 (7.4);
Marks et al., 2009a	Silodosin 8 mg Placebo	*N* = 923 ≥50 years of age with symptomatic BPH (IPSS ≥13, PFR 4–15 mL/s, PVR <250 mL)	12 weeks	IPSS total 8 mg: –6.4 (6.6); (<0.0001) Placebo: –3.5 (5.8)
Chapple et al., 2011	Silodosin 8 mg Placebo	*N* = 1228 ≥50 years of age with symptomatic BPH (IPSS	12 weeks	IPSS total 8 mg: –7.0; (<0.0001) Placebo: –4.7

		≥13, PFR 4–15 mL/s, PVR <250 mL)			

[a]Compared with placebo.

[b]The three most common adverse events are reported if available.

[c]Estimates are significantly different as compared with placebo.

BPH, Benign prostatic hyperplasia; *IPSS,* International Prostate Symptom Score; *NS,* not significant; *PFR,* peak flow rate; *PV,* prostate volume; *PVR,* postvoid residual volume; *QoL,* quality of life; *SD,* standard deviation.

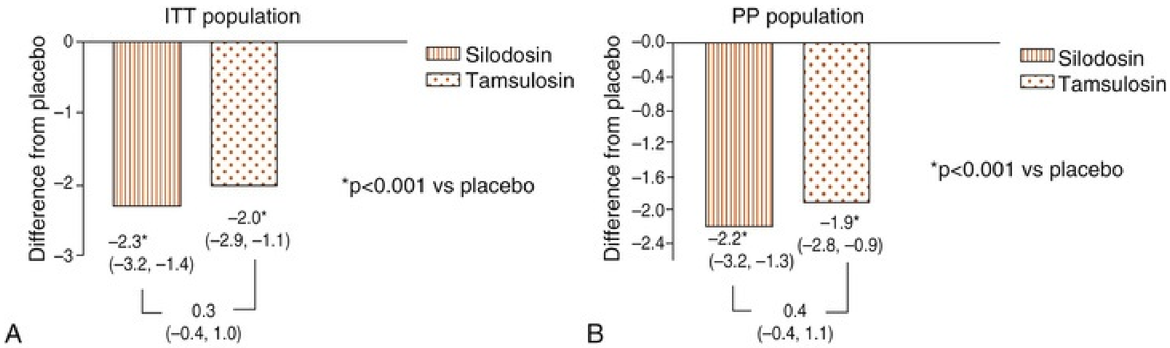

FIG. 145.8 (A and B) Differences from placebo in the total International Prostate Symptom Score. *ITT,* Intention to treat; *PP,* per protocol. (From: Chapple CR, Montorsi F, Tammela TL, et al. Silodosin therapy for lower urinary tract symptoms in men with suspected benign prostatic hyperplasia: results of an international, randomized, double-blind, placebo- and active-controlled clinical trial performed in Europe. *Eur Urol* 59[3]:342–352, 2011. Figure 2, p. 347.)

Two recent meta-analyses provided results of pooled data from the phase III clinical trials on silodosin (Ding et al., 2013; Novara et al., 2013). **Ding et al. (2013) reported a mean change in terms of IPPS storage symptoms score (–0.85; 95% CI, –1.11 to –0.59), IPPS voiding symptoms score (–1.81; 95% CI, –2.21 to –1.42), and QoL score (–0.42; 95% CI, –0.71 to –0.13) that was significantly greater with silodosin than with placebo, with no differences between silodosin and 0.4 mg tamsulosin.** Novara et al. (2013) confirmed these findings. Silodosin demonstrated minimal effects on the cardiovascular system, without any meaningful prolongation of the QT interval and or change of blood pressure. Both meta-analyses confirmed that anejaculation was more likely observed after silodosin treatment compared with either placebo or tamsulosin treatment. In this regard, various reports have well established that anejaculation is linked to silodosin affinity for α_{1a}-ARs (Tatemichi et al., 2012). However, post hoc analysis of phase III studies showed that the odds of achieving a reduction of at least 3 points in the total IPSS and an increase of 3 mL/s for PFR were 1.75 times higher among patients experiencing anejaculation as compared with those who were not (Roehrborn et al., 2011). The discontinuation rates associated with anejaculation were only 1.6% to 2.9% in the phase III trials.

The high selectivity of silodosin for the α_{1a}-AR subtype has also been associated with improvement of urodynamic parameters; indeed, silodosin showed a high mean decrease in terms of BOOI (–30.45; 95% CI, –40.46 to –29.45) (Fusco et al., 2016). Of note, these findings suggest that the perceived overall clinical benefit of this therapy is associated with the main decrease in the detrusor pressure at Qmax as a consequence of the reduction in the magnitude of BOO.

Naftopidil

Naftopidil is the only compound developed with a distinct selectivity for the α_{1d}-AR subtype; preclinical studies showed a threefold higher selectivity for α_{1d}-AR compared with α_{1a}-AR (Ishihama et al., 2006). To date, the drug has been investigated in clinical trials conducted in Japan, but none of these trials were placebo controlled (Table 145.7). Naftopidil was compared with low-dose (0.2 mg/day) tamsulosin in six trials; Ikemoto et al. conducted a randomized crossover study comparing the effect of 8 weeks of therapy with naftopidil at 25 to 50 mg/day followed by therapy with 0.2 mg tamsulosin versus 8 weeks of tamsulosin therapy followed by naftopidil therapy (Ikemoto et al., 2003). There was a significant reduction in terms of total IPSS and QoL score and a significant improvement in urinary flow parameters in both treatment groups without intergroup differences. The noninferiority of naftopidil compared with low-dose tamsulosin was further confirmed in other studies (Gotoh et al., 2005; Momose et al., 2007; Nishino et al., 2006; Ukimura et al., 2008). Naftopidil was found to relieve storage symptoms (e.g., frequency, urgency, and nocturia) with a higher magnitude than low-dose tamsulosin (Nishino et al., 2006; Ukimura et al., 2008). Randomized trials comparing naftopidil with silodosin showed superiority of the latter in terms of IPSS reduction and QoL improvement without differences in terms of uroflowmetry parameters (Shirakawa et al., 2013; Yamaguchi et al., 2013). Moreover, urodynamic data showed an overall change in the BOOI of –16.47 after treatment with naftopidil (Fusco et al., 2016).

TABLE 145.7

Randomized Trials Evaluating the Efficacy and Tolerability of Naftopidil vs. Active Control

	DRUG	PATIENTS	LENGTH OF TREATMENTS	SYMPTOMS (MEAN CHANGE FROM BASELINE [SD]; PERCENTAGE CHANGE [P[a]])
Ikemoto et al., 2003	Naftopidil titrated from 25 to 50 mg Tamsulosin 0.2 mg Crossover study	*N* = 96 Symptomatic BPH patients (IPSS ≥8; PFR <12 mL/s)	8 weeks per drug	IPSS total 50 mg: –6.1 (1.3); NS
Yokoyama et al., 2006	Naftopidil 25 mg Naftopidil 75 mg	*N* = 153 50–80 years of age with symptomatic BPH (PV >20 mL; IPSS ≥8; QoL score >2)	4 weeks	IPSS total 25 mg: –4.5; (NS) 75 mg: –4.6
Yamaguchi et al., 2013	Naftopidil 75 mg Silodosin 8 mg	*N* = 97 Symptomatic BPH patients (IPSS ≥8)	12 weeks	IPSS total: 75 mg: –5.7; (NS) Silodosin: –7.1
Shirakawa	Naftopidil	*N* = 121	8 weeks	IPSS total

et al., 2013	50 mg Silodosin 4 mg twice daily	Symptomatic BPH patients (IPSS ≥8; QoL score ≥3; PFR <12 mL/s; PV ≥20 mL)		50 mg: –7,2 (2.9); (0.004) Silodosin: –2.7 (4.9)

[a] Compared with active control.

[b] The three most common adverse events are reported if available.

AEs, Adverse events; *BPH,* benign prostatic hyperplasia; *IPSS,* International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *PFR,* peak flow rate; *PV,* prostate volume; *QoL,* quality of life; *SD,* standard deviation.

There are different available doses of naftopidil. One study compared a high dose (75 mg) with a low dose (25 mg), showing comparable efficacy in terms of symptom relief, but better results in terms of PFR changes with the higher dose (Yokoyama et al., 2006). However, when the data were stratified for symptom severity, 75-mg naftopidil achieved better results in terms of voiding symptoms in patients with moderate symptoms at the baseline; no significant differences in terms of AEs were observed between the two groups. Recently, evening dosing of naftopidil at 75 mg showed better results in terms of nocturia QoL index compared with morning dosing (Tanaka et al., 2015).

Overall, naftopidil has a good safety profile, with dizziness and hypotension being the most commonly reported AEs. Garimella et al. (2009) conducted a meta-analysis of the available trials assessing the efficacy of naftopidil. The authors concluded that because of the small number of studies and the lack of placebo-controlled trials, a strong conclusion on the efficacy of naftopidil could not be drawn. Moreover, the studies comparing naftopidil with tamsulosin used a low-dose formulation of the latter, which is not currently used in Western countries. Finally, treatment in all studies lasted from 4 to 16 weeks, thus being too short to provide an adequate assessment regarding the safety profile of naftopidil.

Comparison of α-Adrenergic Blockers

Solid evidence for a comparison between available α_1-blockers can be retrieved only from findings of randomized active-controlled trials comparing the effect and tolerability of two different compounds (Table

145.8). The existing discrepancies in study design, patient inclusion criteria, and the modality of recording AEs make the results of single placebo-controlled trials difficult to compare.

TABLE 145.8

Randomized Trials Comparing Different α-Adrenergic Blockers

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (MEAN CHANGE FROM BASELINE [SD]; PERCENTAGE CHANGE [P])
Kaplan et al., 1995	Terazosin 5 mg Doxazosin 4 mg	*N* = 74 >50 years of age with symptomatic BPH (IPSS >12)	52 weeks	Boyarsky total: Terazosin: –4.6; –38 (NS) Doxazosin: –4.9; –42
Na et al., 1998	Terazosin 2 mg Tamsulosin 0.2 mg	*N* = 212 46–83 years of age with symptomatic BPH (IPSS >13)	4 weeks	IPSS total Terazosin: –8.5; –39 (<0.05) Tamsulosin: –9.7; –45
Kirby, 2003	Doxazosin GITS titrated from 4 to 8 mg Tamsulosin titrated	*N* = 42 50–80 years of age with symptomatic BPH (IPSS ≥12; PFR 5–15 mL/s)	8 weeks	IPSS total Doxazosin: –8.0 (0.5); –50 (0.01) Tamsulosin: –6.4 (0.5); –40

	from 0.4 to 0.8 mg Crossover study				
de Reijke and Klarskov, 2004	Doxazosin titrated from 1 to 8 mg Alfuzosin titrated from 5 to 10 mg	*N* = 210 49–80 years of age with symptomatic BPH (IPSS ≥12; PFR 5–15 mL/s)	16 weeks	IPSS total Doxazosin: –9.2 (0.6); –48 (<0.05) Alfuzosin: –7.4 (0.6); –41	
Buzelin et al., 1997b	Alfuzosin 2.5 mg tid Tamsulosin 0.4 mg	*N* = 256 Patients with symptomatic BPH	12 weeks	Boyarsky total Alfuzosin: +39% (NS) Tamsulosin: +40%	
Yu et al., 2011	Silodosin 4 mg bid Tamsulosin 0.2 mg	*N* = 209 ≥40 years of age with symptomatic BPH (IPSS ≥13; PFR <15 mL/s; PVR <250 mL)	12 weeks	IPSS total Silodosin: –7.2 (5.2); (NS) Tamsulosin: –10 (5.1)	
Chapple et al., 2011	Silodosin 8 mg Tamsulosin 0.4 mg	*N* = 1228 ≥50 years of age with symptomatic	12 weeks	IPSS total Silodosin: –7.0; (NS) Tamsulosin: –6.7	

		BPH (IPSS ≥13, PFR 4–15 mL/s, PVR <250 mL)			

[a] The three most common adverse events are reported if available.

[b] Estimates are significantly different between treatment arms.

AEs, Adverse events; *bid,* twice a day; *BPH,* benign prostatic hyperplasia; *GITS,* gastrointestinal therapeutic system; *IPSS,* International Prostate Symptom Score; *NS,* not significant; *PFR,* peak flow rate; *PVR,* postvoid residual volume; *SD,* standard deviation; *tid,* three times a day.

Among nonuroselective α_1-blockers, terazosin and doxazosin have shown a good efficacy profile in terms of both symptom relief and uroflowmetry parameter improvement; both drugs need dose titration to avoid the risk for vascular-related AEs associated with first dosing (see Table 145.1).

Kaplan et al. (1995) compared the effect of 4-mg doxazosin versus 5-mg terazosin in a fixed-dose randomized trial with no significant differences in terms of symptom relief and PFR increase at a mean follow-up of 42 weeks. Likewise, the drugs did not differ in terms of tolerability.

The GITS formulation of doxazosin (4 to 8 mg) was compared with tamsulosin (0.4 to 0.8 mg) in a crossover study (Kirby, 2003); doxazosin therapy resulted a greater reduction in total IPSS than tamsulosin, but no difference was observed in terms of PFR. Both drugs were well tolerated; hypotension was reported by 8.3% of patients in the doxazosin group and 0.4% of patients in the tamsulosin group, although the difference was not significant between groups.

There are no active-controlled trials comparing the alfuzosin once-daily formulation with other α_1-blockers; in a randomized trial with doxazosin versus alfuzosin, dose titration was applied in both treatment groups, and the mean daily treatment dose was 6.1 mg in the doxazosin group and 8.8 mg in the alfuzosin group (de Reijke and Klarskov, 2004). At the end of treatment (16 weeks), patients treated with doxazosin showed a mean percentage symptomatic change of 48% versus 41% in the alfuzosin group ($P < 0.05$). Moreover, no significant differences were observed in terms of reported AEs, although 14.3% of patients discontinued therapy because of AEs in the doxazosin group compared with 6.7% in the alfuzosin group.

Buzelin et al. compared 7.5-mg alfuzosin with 0.4-mg tamsulosin in an active-controlled trial. No differences were observed in terms of both efficacy and tolerability between the drugs, but patients treated with tamsulosin reported a higher rate of retrograde ejaculation. **Both tamsulosin and alfuzosin are uroselective compounds that do not require dose titration and are currently recommended for use at a daily dose of 0.4 mg and 10 mg, respectively** (see Table 145.1). Data from placebo-controlled trials supported comparable efficacy, although alfuzosin was associated with a higher rate of vasodilatory AEs, especially in the elderly and in patients with cardiovascular disease. Conversely, anejaculation was more frequently reported after tamsulosin intake.

Data from two meta-analyses of RCTs comparing silodosin with tamsulosin showed that silodosin was significantly superior to 0.2 mg tamsulosin in terms of total IPSS, voiding symptoms subscore, and QoL; however, no difference was found between silodosin and 0.4 mg tamsulosin (Ding et al., 2013; Novara et al., 2014). Moreover, the two drugs showed comparable rates of AEs and of treatment withdrawal, although the likelihood of reporting anejaculation was significantly higher with silodosin compared with tamsulosin, regardless of the dose used.

Few evidences comparing naftopidil with other α_1-blockers have been published to date, hampering to draw solid conclusions. Overall these data should be interpreted with caution given that the available trials have been conducted only in Asiatic populations and there is large heterogeneity concerning study design and patient selection (Garimella et al., 2009).

Most studies investigating the clinical efficacy profile of α_1-blockers focused on outcomes such as symptom scores and free uroflowmetry parameters; however, urodynamic outcome measures, such as the BOOI, are useful to evaluate the effect of medical therapy on BOO. Fusco et al. (2016) reported the results of a meta-analysis dedicated to urodynamic outcomes after therapy with α_1-blockers; the analysis included a total of 656 patients from 10 observational studies and 7 RCTs. Although a direct comparison of the different compounds was not reported, they performed a subanalysis of data according to each drug investigated, showing a greater decrease of mean BOOI for silodosin as compared with doxazosin, terazosin, alfuzosin, naftopidil, and tamsulosin.

Safety Profile of α_1-Blockers in Specific Patient

Populations

All available α_1-blockers demonstrated an overall good safety profile; however, small differences in terms of AE incidence can be detected among the drugs as a result of their specific α_1-AR subtype selectivity and the different pharmacokinetics profiles.

Treatment-emergent AEs associated with α_1-blockers are caused by the effect of every drug on the vascular tissue, CNS, and urogenital system. Overall, dizziness, asthenia, hypotension, and anejaculation are the most commonly reported AEs according to RCTs.

Hemodynamic Side Effects

Data from RCTs assessing the safety profile of a single α_1-blocker showed a greater incidence of vascular AEs for the nonuroselective compounds terazosin and doxazosin compared with alfuzosin, tamsulosin, and silodosin. **The observed difference in terms of cardiovascular tolerability was related to the higher affinity of nonuroselective compounds for the α_{1b}-AR subtype, which is widely present at the level of vascular tissues. The inhibition of this receptor can lead to a decrease in either systolic or diastolic blood pressure, and to a number of associated events, such as dizziness, asthenia, headache, palpitations, and syncope.**

De Mey et al. (1998) reported data from a direct comparative study using the orthostatic stress test as the most appropriate method to assess the magnitude for interference of drugs with blood pressure. The authors compared 0.4 mg tamsulosin with terazosin titrated from 1 to 5 mg in 50 normotensive men. Terazosin caused significantly more episodes of symptomatic hypotension (defined as a decrease in systolic blood pressure of ≥20 mm Hg with related symptoms) than tamsulosin (36% vs. 4%; $P = 0.01$) (Fig. 145.9). The risk for orthostatic hypotension is considered particularly prominent on initiation of treatment (“first-dose hypotension”); for this reason, dose titration has been advised for both terazosin and doxazosin.

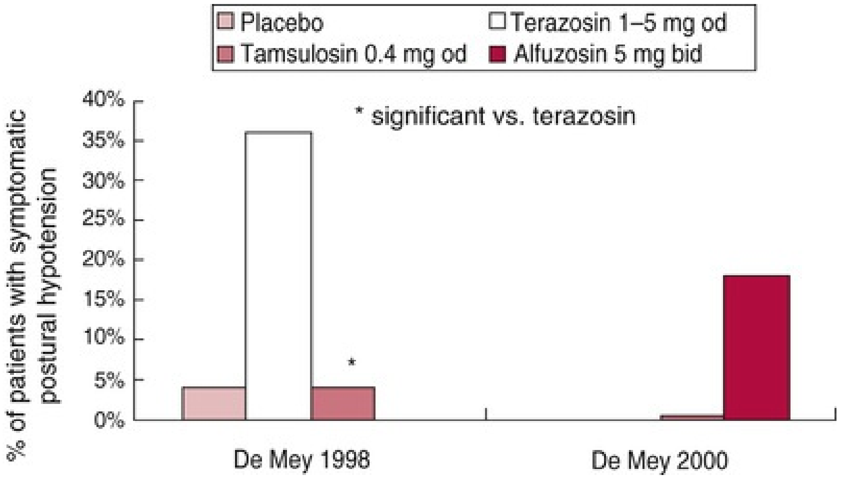

FIG. 145.9 Percentage of patients with symptomatic postural hypotension during orthostatic stress testing in direct comparative studies with 0.4 mg tamsulosin versus terazosin titrated from 1 to 5 mg and 0.4 mg tamsulosin versus 5 mg alfuzosin twice daily. Positive symptomatic postural stress test findings: decrease in systolic blood pressure of 20 mm Hg or more on standing accompanied by symptoms (e.g., dizziness, lightheadedness, and/or syncope). (From: Milani S, Djavan B. Lower urinary tract symptoms suggestive of benign prostatic hyperplasia: latest update on alpha-adrenoceptor antagonists. *BJU Int* 95[Suppl 4]:29–36, 2005. Figure 6, p. 32.)

Indirect comparison of data from placebo-controlled studies showed a higher incidence of dizziness associated with doxazosin and terazosin as compared with both tamsulosin and alfuzosin. The former drugs caused dizziness in 0% to 20% of participants compared with 0% to 8% of participants (corrected for placebo) observed with tamsulosin and alfuzosin (Milani and Djavan, 2005). Dizziness and asthenia have been also reported as the major cause of treatment withdrawal (Roehrborn and Siegel, 1996; Roehrborn et al., 1996). **Of note, commonly reported AEs such as dizziness and asthenia are not exclusively related to the hemodynamic changes associated with the peripheral blockade of α_1-ARs, and are also related to an effect exerted on the CNS.** The pharmacokinetic profile associated with a different speed of onset of blood pressure lowering and the ability of the drug to enter the CNS have been both suggested to play a role in determining the risk for dizziness and asthenia associated with α_1-blockers (Andersson and Gratzke, 2007).

Among uroselective compounds, alfuzosin showed a slightly greater impact on the cardiovascular system compared with tamsulosin; in a direct-comparison randomized trial, 2.5 mg alfuzosin three times daily significantly decreased both supine and standing blood pressure compared with the baseline, whereas 0.4 mg tamsulosin did not (Buzelin et al., 1997b). Similarly, orthostatic stress tests showed that 0.4 mg tamsulosin favored less symptomatic orthostatic hypotension compared with 5 mg alfuzosin twice daily among patients 60 years of age or older (De Mey, 2000) (see Fig. 145.9).

Meta-analyses of RCTs showed that 8 mg silodosin is not associated with a significantly higher risk for hypotension or other vascular AEs compared with placebo (Ding et al., 2013; Novara et al., 2013); similarly no differences were reported in comparison with tamsulosin.

α-Blocker Therapy in Patients With Cardiovascular Diseases

α_1-Blockers were initially developed for the treatment of arterial hypertension, with doxazosin and terazosin originally approved for this indication. Data from RCTs showed that the effect of both drugs on blood pressure is relevant only for patients with hypertension at the baseline (Fawzy et al., 1995; Kirby et al., 1998; Lepor et al., 1997). However, these data have to be interpreted with caution given the heterogeneity among studies in defining a clinically significant hypotensive episode and regarding the method of blood pressure measurement. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) included 24,335 men with hypertension and at least one other coronary risk factor (ALLHAT Collaborative Research Group, 2000). Patients were randomized to receive chlorthalidone, doxazosin, amlodipine, or lisinopril; the finding of a significant increased risk for congestive heart failure in the doxazosin group relative to the chlorthalidone group was the rationale to discontinue the investigation of doxazosin in the antihypertensive trial; data analysis did not show a significant increase of congestive heart failure incidence between doxazosin and the other antihypertensive agents. This trial raised concern on the safety of the use of doxazosin among patients with cardiovascular disease. However, no major cardiovascular AEs have been reported in RCTs assessing the effect of doxazosin for LUTS treatment.

Of clinical relevance, concomitant medications in patients with LUTS and cardiovascular disease should be taken into account when patients are being counseled for treatment. Alfuzosin, for instance, has been associated with an increased risk for cardiovascular AEs among patients with concomitant antihypertensive or vasodilating medications (Lukacs et al., 1996, 2000). Conversely, tamsulosin did not show a significant interaction with different antihypertensive agents (e.g., β-blockers, calcium antagonists, angiotensin-converting enzyme inhibitors) (Lowe, 1997); similarly, in a pooled analysis including almost 20,000 patients from two RCTs, the tolerability of tamsulosin did not differ for patients with hypertension or other cardiovascular diseases (Michel et al., 1998). Likewise, silodosin did not show differences in terms of cardiovascular AEs between patients treated with concomitant antihypertensive medications and normotensive men (Novara et al., 2014).

Overall, α_1-blockers should be carefully administered in patients taking antihypertensive medications. The concomitant use of α_1-blockers with other α-blocker compounds is not recommended.

α_1-Blockers in the Elderly

The tolerability profile of α_1-blockers appears more relevant in the elderly population; **AEs such as dizziness and orthostatic hypotension may lead to falls, fractures, and institutionalization in older patients.** Indeed, older patients have a less dynamic adaptation to orthostatic stress and a reduced vascular compliance as they tend to rely more on the homeostatic contribution of ancillary vasoconstriction (Milani and Djavan, 2005).

The nonuroselective compounds terazosin and doxazosin could be less tolerated by elderly men, although pooled analyses of multicenter RCTs of terazosin (Wilt et al., 2002a) and doxazosin (Kaplan and D'Alisera, 1998) did not show any age-dependent incidence of AEs. However, it should be noted that most of those trials included highly selected patients.

Among uroselective compounds, open-label studies showed that alfuzosin was associated with more cardiovascular AEs in patients older than 75 years of age (Lukacs et al., 1996, 2000). In the Osteoporotic Fractures in Men study, including 5,872 men 65 years of age or older, Parsons et al. (2009) reported that the risk for falls was significantly associated with moderate to severe LUTS, suggesting a negative influence of LUTS medications. Similarly, in a recent population-based cohort study including 147,084 men 66 years of age or older and prescribed alfuzosin, tamsulosin, or silodosin, the risk for falling and of sustaining fractures was significantly higher compared with that in a matched-control unexposed cohort (Welk et al., 2015).

Bird et al. (2013) looked at the US health care claims data for men 40 to 85 years of age who were first prescribed tamsulosin or a 5ARI and who developed hypotension requiring hospital admission. They observed an increased rate of severe hypotension with tamsulosin treatment (42.4 events per 10,000 person-years) versus 5ARI treatment (31.3 events per 10,000 person-years). This was particularly significant within the first 8 weeks of new drug use. Therefore, **physicians should warn patients regarding a risk for first-dose hypotension with α_1-blockers**.

In a subanalysis of individual patient data from registration trials of silodosin, the prevalences of dizziness and orthostatic hypotension were similar between patients younger than 65 years of age and patients older than 65 years of age (Novara et al., 2015). Similarly, in a study including patients older than 65 years of age taking antihypertensive medications and firstly prescribed silodosin, Choi et al. (2017) did not find evidence of changes in blood pressure associated with treatment.

α_1-Blockers and Sexual Function

There is a proved link between sexual dysfunction and LUTS (Rosen et al., 2003); in this context, the impact of α_1-blockers on sexual function has been comprehensively investigated (Gacci et al., 2011, 2014). **Positive effects of α_1-blockers on erectile function have been variably observed and ascribed to the beneficial effect of these drugs in terms of LUTS relief and QoL improvement** (Gacci et al., 2011; Van Dijk et al., 2006); moreover, there is evidence showing that α-AR inhibition within cavernosal tissue may lead to smooth muscle relaxation and to a consequent enhancement of the erection (Goldstein 2000). Data from RCTs showed a comparable incidence of erectile dysfunction between α_1-blockers and placebo (MacDonald and Wilt, 2005; MacDonald et al., 2004; Wilt et al., 2002a). In a meta-analysis conducted by the AUA, the overall incidence of erectile dysfunction associated with α_1-blocker therapy was 3% to 5% (AUA Practice Guidelines Committee, 2003). Similarly, pooled data analysis showed no significant impact of these drugs on sexual desire (Van Dijk et al., 2006).

Ejaculation disorders also have been associated with α_1-blocker therapy (Gacci et al., 2014); smooth muscle inhibition at the level of the bladder neck was originally considered the main reason for retrograde ejaculation; furthermore, a direct effect of α_1-blockers on seminal vesicles leading to anejaculation has also been proposed (Andersson and Gratzke, 2007). Moreover, data on tamsulosin also suggested a central effect on the control of ejaculation mediated by binding to the D_2-like and 5-HT_{1A} receptors (Giuliano, 2006). Overall, **the nonselective compounds doxazosin and terazosin did not show a detrimental effect on ejaculation in RCTs.**

Tamsulosin at 0.8 mg has been associated with an 18% incidence of anejaculation (Wilt et al., 2003). However, silodosin showed an even higher incidence of ejaculation disorders when compared with tamsulosin in a multicenter trial (14% vs. 2%) (Chapple et al., 2011). These findings were confirmed by a meta-analysis **including data from 10 randomized trials, showing that the odds of reporting ejaculation disorders was significantly higher for silodosin (odds ratio, 32.5; $P < 0.001$) than for tamsulosin (odds ratio, 8.57; $P = 0.006$)** (Gacci et al., 2014). Moreover, in a real-life study, Capogrosso et al. showed that almost 70% of patients reported either anejaculation or hypospermia after treatment with silodosin, with a concomitant orgasmic function impairment in 17% of the patients (Capogrosso et al., 2015). Younger patients showed higher rates of a concomitant impairment of ejaculation and orgasmic function (Capogrosso et al., 2015).

Other Complications Associated with α-Blocker Therapy

Intraoperative floppy iris syndrome (IFIS) was firstly reported after the intake of tamsulosin (Chang and Campbell, 2005); **the syndrome occurs during cataract surgery, and is characterized by a floppy iris that flutters and billows in response to normal intraoperative fluid movement, a prolapse of iris tissue toward surgical incisions, and a progressive intraoperative miosis despite standard preoperative pupil dilation.** This triad of symptoms is not always present, and most patients show only one or two signs. The occurrence of IFIS has been associated with the blockade of the α_{1a}-AR subtype at the level of the iris dilator muscle, although the exact pathophysiology is still under debate. IFIS has also been reported several years after drug use discontinuation (Nguyen et al., 2007); in this context, it was suggested that the pharmacologic inhibition of iris smooth muscle can lead to muscle atrophy in the long term. Indeed, structural changes of iris tissue have been observed in patients taking α_1-blockers (Santaella et al., 2010).

The incidence of IFIS differs among different drugs: a rate of 30% to 88% has been reported for patients treated with tamsulosin, compared with 15% to 70%

for alfuzosin, 2% to 45% for doxazosin, and 19% for naftopidil (Oelke et al., 2014). No significant data have been reported regarding the occurrence of IFIS among patients treated with silodosin, although this issue has not been specifically investigated. A meta-analysis assessing the risk for IFIS among individuals taking α_1-blockers confirmed the higher incidence of this syndrome after therapy with tamsulosin as compared with the other compounds (Chatziralli et al., 2011). **Discontinuation of the use of drug before cataract surgery does not significantly reduce the risk for IFIS. Therefore, cataract surgeons should ask about either current or previous use of α_1-blockers and be prepared to manage the complications. Similarly, the prescribing physician should counsel patients regarding the need to report the use of α_1-blockers to the ophthalmologist.**

Summary

Efficacy and safety profiles of α_1-blockers in men with LUTS have been largely described in multicenter RCTs. Published data showed a significant reduction of symptom scores and improvement of uroflowmetry parameters associated with α_1-blockers therapy, along with an excellent safety profile. Asthenia, dizziness, anejaculation, and orthostatic hypotension are the main treatment-emergent AEs. Moreover, longitudinal trials have provided evidence for the long-term efficacy and safety of these drugs.

Few studies directly compared the different α_1-blockers, thus hampering the ability to draw a conclusion in terms of superiority of one drug over the others concerning efficacy. However, there is a major distinction between nonuroselective and uroselective drugs depicting a different safety profile: the latest released uroselective drugs tamsulosin and silodosin showed a lower risk for vascular AEs compared with the nonuroselective drugs doxazosin and terazosin. On the other hand, the uroselective compounds are associated with a higher risk for ejaculatory disorders.

International clinical guidelines suggest α_1-blockers as the first-line treatment in patients with bothersome moderate to severe LUTS. Patients should be counseled before treatment regarding the risk for sexual and vascular side effects associated with this therapy. It is advised to monitor blood pressure during the first week of treatment.

Androgen Manipulation

Hormonal therapy for BPH has been clinically investigated since the 1970s and still has an important role in the therapeutic armamentarium for patients with LUTS caused by BPE.

Rationale for Androgen Manipulation

Prostate tissue is androgen dependent, and both testosterone and dihydrotestosterone (DHT) play a key role in the development of BPH (Coffey and Walsh 1990; Shapiro 1990). The potent male sex hormone DHT is a metabolite of testosterone and is synthesized by two isoenzymes: type 1 and type 2 5α-reductase. Of these, the type 2 isoenzyme is mainly expressed at the level of the prostate and genital tissues; the type 1 isoenzyme is present in several organs other than the prostate, such as the liver and the skin.

Through binding with androgen receptors, both DHT and testosterone act as chemical messengers for the process of prostate growth and cellular function. Although the two hormones are capable of binding androgen receptors, DHT tends to dissociate more slowly and is intrinsically more potent than testosterone at the prostate level (Andriole et al., 2004).

Castration and pharmacologic agents suppressing testosterone and DHT synthesis or action are able to reduce PV in men with BPH (McConnell 1990). Reducing PV is thought to decrease the static component of BOO in BPH patients. However, the first limitation of the androgen suppression hypothesis is that LUTS pathophysiology is not entirely dependent on prostate size.

Classification of Pharmacologic Agents

Surgical castration was reported to be effective in reducing the volume of an enlarged prostate in the 1890s (White, 1895; Cabot, 1896). Scott and Wade (1969) were first to report the effect of medical castration as a treatment of LUTS associated with BPE. They investigated the effect of a progestational antiandrogen (cyproterone acetate) on prostate tissue; the drug was able to induce prostate atrophy by suppressing steroid synthesis at the level of the testes, without suppressing luteinizing hormone. Furthermore, other nonsteroidal drugs (e.g., flutamide, bicalutamide) blocking the binding of testosterone and DHT to the androgen receptor were investigated for the treatment of BPH (Caine et al., 1975; Eri and Tveter, 1993). Similarly, a regression of prostatic enlargement was clinically observed with gonadotropin-releasing hormone (GnRH) analogues (Schroeder et al., 1986), but all of these compounds were associated with AEs related to the alteration of the hypothalamic-pituitary-gonadal (HPG) axis and of the overall hormonal milieu. Conversely, 5ARIs are able to block the conversion of testosterone to DHT in prostatic stroma cells by inhibiting the enzyme 5α-reductase, without a significant interaction with the HPG axis. The pharmacologic strategies of androgen suppression that have been investigated for LUTS and BPH in the past three decades are summarized in Table 145.9.

TABLE 145.9

Androgen Manipulation: Classification of Pharmacologic Agents and Dosages

DRUGS	DOSAGE	REFERENCE
GONADOTROPIN-RELEASING HORMONE ANALOGUES		
Leuprolide	3.75 mg IM monthly	Schroeder et al., 1986
		Keane et al., 1988
		Eri and Tveter, 1993
Nafarelin acetate	400 mg SC qd	Peters and Walsh, 1987
Cetrorelix	1 mg SC qd ± loading dose	Lepor et al., 1997
	Three dosage regimens	Debruyne et al., 2008
PROGESTATIONAL AGENTS		
17α-Hydroxycortisone	200 mg IM weekly	Meiraz et al., 1977
Megestrol	250 mg PO tid	Donkervoort et al., 1975
	40 mg PO tid	Geller et al., 1979
ANTIANDROGENS		
Flutamide	100 mg tid	Caine et al., 1975
	250 mg tid	Stone, 1989
Oxandrolone	200 mg IM weekly	Ostri et al., 1989
Bicalutamide	50 mg qd	Eri and Tveter, 1993
Zanoterone	100–800 mg qd	Berger et al., 1995
Chlormadinone acetate	50 mg qd	Fujimoto et al., 2013
		Warnings and important notices
5α-REDUCTASE INHIBITORS		

Finasteride	5 mg qd. Treatment is recommended for at least 6 months	• PSA levels decrease by approximately 50% • Finasteride is not indicated for PCa prevention because of an observed increased risk for high-risk disease • Patients should be warned regarding risk for sexual dysfunction and depression
Dutasteride	0.5 mg qd. Treatment is recommended for at least 6 months	• PSA levels decrease by approximately 50% • Dutasteride is not indicated for PCa prevention because of an observed increased risk for high-risk disease • Patients should be warned regarding risk for sexual dysfunction and depression

IM, Intramuscularly; *PCa,* prostate cancer; *PO,* per os; *qd,* once a day; *SC,* subcutaneously; *tid,* three times a day.

Interpreting the Literature on Androgen Manipulation

Because the maximal PV reduction is achieved within 6 months after initiation of androgen suppression (Gormley et al., 1992; Peters and Walsh, 1987), **the outcomes of RCTs should be considered reliable only for time points at or after 6 months from the beginning of treatment.** Moreover, several data showed that patients with larger PV are likely to achieve the greatest therapeutic benefit (McConnell et al., 1998, Tacklind et al., 2010). **In this context, most of the published RCTs enrolled men with larger prostates, and therefore the reported results may not be representative of the overall population of patients with BPH.**

Treatment-emergent AEs after 5ARI therapy may have been overlooked and underestimated in trials that were not designed to assess specific drug-related side effects as primary or secondary end points. Indeed, the U.S. Food and Drug Administration (FDA) reviewed the safety profile of 5ARIs in 2011 given the new emerging evidence supporting a risk for depressive symptoms and sexual dysfunction associated with these drugs. Similarly, results concerning the metabolic and cardiovascular safety of these drugs should be interpreted with caution given the heterogeneity in the interpretation and recording of AEs among different studies.

Review of the Literature

Several nonrandomized studies evaluated the effects of androgen manipulation on the outcomes of patients with BPH**; the 5ARIs finasteride and dutasteride currently represent the paradigm for androgen suppression in the treatment of BPH.** This section considers the multicenter RCTs investigating the efficacy and safety profile of finasteride and dutasteride.

Finasteride

Finasteride is a selective inhibitor of the type 2, 5α-reductase isozyme (Vermeulen et al., 1989) and is responsible for decreasing intraprostatic DHT levels without reaching a castration level because of the remaining activity of the type 1 5α-reductase isozyme converting serum testosterone to DHT at the level of the skin and liver (Thigpen et al., 1993).

The results of the most relevant RCTs assessing the efficacy and safety of finasteride are summarized in Table 145.10. In the first multicenter, randomized, double-blind, placebo-controlled trial (the North American Finasteride Trial), Gormley et al. (1992) evaluated the effect of either 1 mg or 5 mg finasteride given once daily for 12 months in 895 patients with BPH (Gormley et al., 1992). Patients were selected on the basis of symptoms and urinary flow parameters (Qmax <15 mL/s). Mean PV at the baseline was approximately 60 mL. Data showed significant symptomatic relief in men treated with 5 mg finasteride as compared with placebo, with a maximal decrease of 2.7 points on the Boyarsky scale after 12 months; similarly, urinary flow rate increased in both active treatment groups compared with the placebo group, with a larger effect observed for the 5-mg group (mean PFR increase, 1.6 mL/s). **The authors observed a progressive decrease in PV in both finasteride groups; after 12 months of treatment, the mean reduction in PV from the baseline was 19% in men treated with 5 mg finasteride**. The changes in PV were not directly related to the magnitude of the clinical response to finasteride, suggesting that the efficacy of finasteride may not be mediated exclusively by reduction of PV. At the same time, a significant reduction in serum PSA level was reported starting after 3 months of treatment. The median decrease in serum PSA level was 50% from the baseline in the 5-mg group. **The drug was overall well tolerated: the most frequently observed AEs in the 5-mg group were decreased libido (4.7%) and ejaculatory disorders (4.4%)**. In the 1-mg treatment group, 5% of patients reported impotence, which was significantly higher than with placebo.

TABLE 145.10

Placebo-Controlled Trials Assessing Finasteride for Treatment of Benign Prostatic Hyperplasia

	DRUG	PATIENTS	LENGTH OF TREATMENT	SYMPTOMS (MEAN CHANGE FROM BASELINE; PERCENTAGE CHANGE [P[a]])
Gormley et al., 1992	Finasteride 1 mg Finasteride 5 mg Placebo	*N* = 895 40–83 years of age with symptomatic BPH (PFR <15 mL/s)	12 months	Boyarsky total 1 mg: –9% (NS) 5 mg: –21% (<0.05) Placebo: –2%
Andersen et al., 1995	Finasteride 5 mg Placebo	*N* = 707 <80 years of age with symptomatic BPH (PFR 5–15 mL/s, PVR ≤150 mL)	24 months	Boyarsky total 5 mg: –2.0; (<0.01) Placebo: +0.2
Marberger, 1998	Finasteride 5 mg	*N* = 3270 50–75 years	24 months	Boyarsky total 5 mg: –3.1;

	Placebo	of age with symptomatic BPH (PFR 5–15 mL/s; PSA <10 ng/mL)		(<0.01) Placebo: –1.5	
McConnell et al., 1998	Finasteride 5 mg Placebo	*N* = 3040 Symptomatic BPH patients (PFR <15 mL/s; PSA <10 ng/mL)	48 months	IPSS total 5 mg: –1.6; (<0.001) Placebo: –1.0	

[a] Compared with placebo.

[c] Estimates are significantly different between treatment arms.

BPH, Benign prostatic hyperplasia; *IPSS,* International Prostate Symptom Score; *NS,* not significant; *PFR,* peak flow rate; *PSA,* prostate-specific antigen; *PVR,* postvoid residual volume.

To evaluate the effect of finasteride in terms of disease progression, Andersen et al. (1995) conducted a 2-year multicenter RCT. A total of 707 patients with LUTS associated with prostate enlargement on DRE (mean volume at the baseline, 40 mL) were randomized to receive 5 mg finasteride or placebo. The authors observed a reduction in symptom score in both groups. However, the placebo effect disappeared after 8 months, and patients had returned to baseline values at the 24-month assessment. Conversely, the symptom scores steadily decreased in the finasteride group, reaching a mean decrease of 2 points at the end of the study period. Likewise, a 1.5 mL/s mean increase in PFR was observed in the finasteride group, and PV decreased by 17.9% after 12 months of treatment and was maintained after 24 months, along with a 52% reduction in PSA value. **Fewer patients in the finasteride group as compared with the placebo group developed urinary retention or needed prostate surgery.** The overall rate of AEs was similar between the groups, although a higher rate of sexual dysfunctions was observed in the finasteride group than in the placebo group (19% vs. 10%).

In the open-label extension of the North American and International Finasteride trial, Stoner (1994) reported the results after 3 years of treatment. A total of 297 patients treated with 5 mg finasteride completed the 3-year trial. After 36 months of treatment, 42% of patients showed a decrease in PV of 30% or more. The effects on symptom score and urinary flow parameters were also maintained after 3 years of treatment, with most changes observed between 12 and 18 months after the beginning of treatment. Sexual dysfunction (erectile dysfunction, decreased libido, and ejaculation disorders) was reported by 10.8% of patients in the finasteride group and 5.2% in the placebo group. These results were further confirmed in a 5-year open-label extension trial on the same population (Hudson et al., 1999).

The Proscar Long-Term Efficacy and Safety Study (PLESS) represented, at the time, the longest-duration multicenter RCT ever reported in terms of BPH medical therapy (McConnell et al., 1998). The study enrolled 3040 men with a mean PV of 55 mL and moderate to severe symptoms treated with finasteride or placebo and followed up for 4 years. The effects on urinary flow rate and PV were comparable with those in the previously published trials. Of note, the authors assessed the rate of occurrence of AUR and surgery for BPH: patients treated with finasteride showed a 51% reduction in the risk for either AUR or surgery compared with patients given placebo. The cumulative incidence of AUR after 4 years was 7% in the finasteride group and 3% in the placebo group (57% risk reduction). The cumulative risk rates for undergoing BPH-related surgery were 10% in the placebo group and 5% in the finasteride group (55% risk reduction). In men with PV greater than 55 mL, the risk reduction for AUR and/or surgical intervention after finasteride treatment was 70%. Men with significantly enlarged prostates should be advised about the risk for urinary retention and the beneficial effects of finasteride therapy. Finasteride is recommended at the daily dose of 5 mg with or without a meal (see Table 145.9); patients should be informed that although early improvement could be seen, treatment for at least 6 months may be necessary to perceive a beneficial effect.

In a meta-analysis including 19 placebo-controlled trials of finasteride, Tacklind et al. (2010) confirmed moderate relief of symptoms after 1 year of treatment with finasteride and a significant decrease in the risk for disease progression and AUR. Moreover, the results showed that patients with a prostate larger than 40 mL appeared to benefit the most from treatment.

The PCPT showed that **finasteride reduced the incidence of diagnosed PCa** (vs. placebo), although an increased incidence of high-grade disease was observed, possibly because of a volume change effect (Thompson et al., 2003).

Finasteride has been demonstrated to significantly decrease serum PSA levels by approximately 50%; in terms of PCa detection, results from PCPT demonstrated that treatment with finasteride significantly increases the sensitivity of the PSA test in predicting PCa (Thompson et al., 2006).

Finally, the effect of finasteride in preventing gross hematuria secondary to BPH has also been investigated: in an RCT, gross refractory hematuria recurred within 1 year in 63% of men randomized to receive placebo and in 14% of men randomized to receive finasteride (Foley et al., 2000).

Dutasteride

Dutasteride is a dual inhibitor of 5α-reductase types 1 and 2. Because of the inhibition of both isozymes, dutasteride leads to a greater decrease of serum DHT levels compared with finasteride (Clark et al., 2004). Table 145.11 details RCTs assessing the efficacy and safety profile of dutasteride as compared with placebo.

TABLE 145.11

Placebo-Controlled Trials Assessing Dutasteride for Treatment of Benign Prostatic Hyperplasia

DRUG	PATIENTS	LENGTH OF	SYMPTOMS (MEAN CHANGE FROM

			TREATMENT	**BASELINE [SD]; PERCENTAGE CHANGE [P[a]])**
Roehrborn et al., 2002	Dutasteride 0.5 mg Placebo	*N* = 4325 ≥50 years of age with symptomatic BPH (IPSS ≥12, PFR ≤15 mL/s; PV ≥30 mL; PSA 1.5–10 ng/mL)	24 months	IPSS total 0.5 mg: –4.5 (6.6): (<0.001) Placebo: –2.3 (6.8)
Clark et al., 2004	Dutasteride 0.5 mg Placebo	*N* = 132 ≥50 years of age with symptomatic BPH (IPSS ≥8, PFR ≤15 mL/s; PV ≥30 mL)	6 months	NR
Tsukamoto et al., 2009	Dutasteride 0.5 mg Placebo	*N* = 253 ≥50 years of age with symptomatic BPH (IPSS ≥8, PFR ≤15 mL/s; PV ≥30 mL)	12 months	IPSS total 0.5 mg: –5.3; (<0.05) Placebo: –3.7

Roehrborn et al. (2002) performed a multicenter RCT that enrolled 4325 men treated with either dutasteride at 0.5 mg daily or placebo for 24 months. Patients were included if they had moderate to severe symptoms, a PFR of 15 mL/s or less, and a PV of 30 mL or more. There was a 90.2% decrease in serum DHT level among patients who received dutasteride. At the end of study treatment, the mean reduction in the symptom score from the baseline was 4.5 after dutasteride treatment and 2.3 with placebo ($P < 0.001$) (Fig. 145.10); moreover, PFR increased by 2.2 mL/s on average, and PV was reduced by a mean of 25.7% after 24 months in the active treatment group. The risk reduction for AUR and BPH surgery was 57% and 48%, respectively, with dutasteride ($P < 0.001$; Fig. 145.11). Overall, dutasteride was well tolerated; **the most frequent AEs were erectile dysfunction and decreased libido, observed in 6% and 3.7% of patients, respectively, after 1 year of treatment; however, these rates significantly dropped after 2 years of treatment.** These results were further confirmed in other smaller randomized trials (Clark et al., 2004; Na et al., 2012; Tsukamoto et al., 2009) (see Table 145.11).

FIG. 145.11 Kaplan-Meier estimates for the first episode of (A) acute urinary retention and (B) BPH-related surgical intervention according to the treatment arms. (From Roehrborn CG, Boyle P, Nickel JC, et al. Efficacy and safety of a dual inhibitor of 5-alpha-reductase types 1 and 2 (dutasteride) in men with benign prostatic hyperplasia. *Urology* 60[3]:434–441, 2002. Figure 3, p. 438.)

Debruyne et al. (2004) reported the results of a 4-year open-label extension of a multicenter trial comparing dutasteride and placebo. Patients treated with dutasteride during the randomized trial continued the therapy for another 24 months; conversely, those previously randomized to receive placebo were switched to dutasteride for 2 years. There was further relief of symptoms and improvement of uroflow parameters at 48 months. Patients who received dutasteride throughout the entire 4-year treatment period did not show a significant further reduction in PV from 24 to 48 months. AUR and BPH surgery were rarely observed from month 24 to month 48. A decrease in the incidence of sexual AEs in the last 2 years of treatment was also observed.

A recent meta-analysis including RCTs assessing the effect of dutasteride versus placebo for the treatment of BPH confirmed the efficacy of the drug in relieving urinary symptoms and improving uroflow parameters, with a mean symptom score reduction of 1.78 and a PFR increase of 1.27 mL/s; moreover, pooled analyses showed a mean reduction in PV of 17.40 mL (Park and Choi, 2014). **Dutasteride is recommended at the daily dose of 0.5 mg with or without a meal; a long-term treatment (at least 6 months) is usually needed to observe a clinical benefit** (see Table 145.9).

Data comparing finasteride and dutasteride were reported in only two studies (Clark et al., 2004; Nickel et al., 2011). In the larger trial, Nickel et al. (2011) compared data from 813 patients treated with dutasteride with data from 817 patients receiving finasteride in a randomized, double-blind fashion. **After 1 year of treatment, there was no difference in terms of symptom relief and PFR increase between patients treated with dutasteride and patients treated with finasteride; similarly, the reduction of PV was comparable between the groups.** Both drugs were well tolerated, without significant differences in the incidence of AEs. These results confirmed the findings of a previous trial (Clark et al., 2004).

In the REDUCE trial, Andriole et al. (2010) investigated the effect of dutasteride versus placebo in preventing PCa in a population of patients with

BPH and a previous negative prostate biopsy result. **There was a 23% relative reduction in the risk for PCa within 4 years of treatment with dutasteride. However, a small increase in the number of cancers with a Gleason score of 8 or more was observed in the treatment arm.** Therefore, in December 2010 the FDA Oncologic Drugs Advisory Committee voted against the use of dutasteride for reducing the risk for PCa, and the manufacturer has withdrawn the application.

As for finasteride, a 50% reduction in the PSA level has to be expected with dutasteride treatment; in this context, data from the REDUCE trial showed that treatment with dutasteride can improve the accuracy of PSA testing in predicting biopsy outcomes (Vickers and Sjoberg, 2015).

Zanoterone

Zanoterone is a steroidal competitive androgen receptor antagonist (Juniewicz et al., 1993). Previously investigated androgen receptor antagonists, in the context of BPH treatment, have shown several drawbacks associated with interference with the HPG axis.

Zanoterone was investigated in a multicenter RCT including 463 patients receiving either placebo or 100-, 200-, 400- or 800-mg zanoterone for 6 months (Berger et al., 1995). There was a significant mean increase in PFR only in the 200-mg group (1.7 mL/s; $P = 0.02$). No significant difference was observed between any treatment dose and placebo in terms of symptom score reduction and PV reduction. Moreover, there was a significant increase in estradiol and testosterone serum concentrations; similarly, a higher incidence of AEs such as breast pain and gynecomastia were observed in the zanoterone group as compared with the placebo group. Overall, the observed minimal efficacy and the greater than expected frequency of AEs led to early trial discontinuation and precluded further development of this drug for treatment of LUTS/BPH.

Flutamide

Flutamide is a nonsteroidal antiandrogen that inhibits the binding of testosterone and DHT to the androgen receptor. In the first double-blind placebo-controlled study, 30 patients with symptomatic BPH were randomized to receive flutamide at 300 mg/day versus placebo (Caine et al., 1975). There was no significant difference in terms of symptom relief, PV changes, and urinary flow parameter improvement between flutamide and placebo. In a multicenter, randomized, double-blind trial, flutamide at 250 mg three times a day for 6 months was compared with placebo (Stone, 1989). The study included patients with obstructive BPH according to uroflowmetry measurements. Of 84 patients included, 58 (69%) were evaluable at 12 weeks and 12 (14%) were evaluable at 24 weeks on double-blind treatment. The small sample size at 24 weeks precluded any meaningful conclusions. **The between-group comparisons of mean changes from the baseline in the investigated outcomes were not statistically significant at any time point.** The incidences of breast tenderness and diarrhea after flutamide treatment were 53% and 11%, respectively. In a further multicenter randomized trial including 372 patients, the authors tested different doses of flutamide (125 mg twice daily; 250 mg once daily; 250 mg twice daily; 250 mg three times daily) versus placebo. There was a dose-dependent decrease of PV, with a maximum of –24% after 6 months. No significant difference between placebo and flutamide was observed in terms of any other efficacy outcome. From 25% to 39% of patients in the flutamide groups discontinued treatment because of diarrhea or breast tenderness.

Cetrorelix

Cetrorelix is a GnRH antagonist allowing a submaximal, noncastrating blockade of testosterone and DHT. The advantage of cetrorelix, as compared with other GnRH agonists, is the ability to titrate the level of androgen suppression. This would be clinically relevant if different levels of androgen suppression mediate prostate size reduction and AEs (hot flashes, decreased libido, impotence). In an open-label phase I/II study, 13 patients with symptomatic BPH were treated with subcutaneous injection of cetrorelix administered at 5 mg for the first 2 days (loading dose) and at 1 mg/day for 2 months (Comaru-Schally et al., 1998). At the end of treatment, IPSSs decreased by a mean of 11.7 points. Symptom scores continued to decrease after treatment discontinuation, reaching a 61% mean decrease at the end of the follow-up period (18 months). Mean PV decreased by 27% after 2 months of treatment; however, PV slightly increased after treatment discontinuation. Total testosterone level reached castration levels after the loading dose, but during maintenance treatment was inhibited by only 64% to 74%. Up to 77% of men reported decreased libido and nocturnal penile tumescence at the end of treatment. Debruyne et al. (2008) tested three regimens of cetrorelix in a double-blind, placebo-controlled, randomized trial. In this study, 140 patients with BPH were randomized to receive subcutaneous injections of cetrorelix at 5 mg per week for 4 weeks versus 10 mg every 2 weeks for 2 weeks versus 10 mg per week for 4 weeks versus placebo. In all treatment groups, the IPSS rapidly decreased, with a peak effect of –5.4 to –5.9 points; 4 months after the end of the treatment, the reduction in the symptom score was significantly higher in all treatment groups compared with the placebo group. Similarly, urinary flow parameters showed a significant and persistent improvement after cetrorelix treatment compared with placebo. A significant and persistent decrease in PV from the baseline was observed only in the group receiving 10 mg cetrorelix. Moreover, the authors did not report any clinically significant change in sexual function. These results, showing a rapid onset of relief of symptoms lasting well beyond the end of treatment, suggested the possibility of an intermittent dosage regimen to treat patients with BPH. In a subsequent randomized placebo-controlled trial investigating an SR intramuscular formulation of cetrorelix, symptom relief lasted up to 6 months after 2 weeks of treatment (Debruyne et al., 2010).

The primary disadvantages of cetrorelix was the requirement for an injection and the cost; if further data prove that a single-injection therapy provides a desirable clinical response (e.g., over 6 months) with minimal side effects, there may be a role for this antagonist in the treatment of LUTS/BPH.

Chlormadinone Acetate

Chlormadinone acetate (CMA) is a steroid antiandrogen that inhibits the uptake of testosterone by epithelial cells and the binding of DHT to the androgen receptor within the cell. Treatment with CMA has been shown to reduce testosterone levels by approximately 90% (Fujimoto et al., 2013). In a multicenter, noncontrolled, prospective study, 115 patients with symptomatic BPH were treated with 25 mg CMA twice daily or 50 mg once daily for a total of 16 weeks and were followed up to 48 weeks (Fujimoto et al., 2013). There was significant reduction in IPSS starting 8 weeks after treatment and lasting until the end of follow-up. The mean PFR increased to a maximum of 1.96 mL/s at week 16 and remained elevated until week 48. Similarly, a 25% decrease in PV was observed after 16 weeks of treatment. A significant deterioration of erectile function was observed at the end of treatment.

Aromatase Inhibitors

Preclinical data have demonstrated a role for estrogens in the pathogenesis of BPH. Their binding to estrogen receptors, at the level of stromal cells, may influence proliferation and differentiation. The role of prostatic mesenchyme (stroma) in the development of BPH is supported by the observation of Cunha et al. (1980) in a mouse embryonic animal model. Moreover, treatment of male dogs with both androgens and estrogens led to earlier and more extensive BPH (Coffey and Walsh, 1990); indeed, estrogens can also greatly enhance the ability of androgens to induce BPH, as shown in other preclinical studies (Walsh and Wilson, 1976; DeKlerk et al., 1979).

Aromatase inhibitors are able to block the conversion of testosterone to estrogens in tissues by inhibiting the enzyme aromatase.

Atamestane is a highly selective aromatase inhibitor that lowers both serum and intraprostatic levels of estradiol and estrone (el Etreby et al., 1991). In a multicenter RCT, 160 patients with symptomatic BPH were treated with 40 mg (Gingell et al., 1995). There was a significant decrease in serum estrogen levels and a 15% decrease in PV. **However, there was no relief of symptoms or improvement of urinary flow parameters. Moreover, a dose-dependent increase in peripheral androgen concentration was observed, and this may be the reason for the lack of efficacy of the drug.** However, in a randomized trial including 88 hypogonadal men, treatment with the aromatase inhibitor anastrozole did not result in significant relief of symptoms, despite the low level of serum testosterone (Burnett-Bowie et al., 2009).

Selective Estrogen and Androgen Receptor Modulators

Therapeutic selective estrogen receptor modulators (SERMs) have been used for PCa prevention and for the amelioration of side effects associated with androgen ablation therapy in patients with advanced disease. They act by modulating the activity of the estrogen receptor, exerting an enhancing or inhibitory effect according to the different receptor types (Ellem and Risbridger, 2007). This modulation can translate into an antiproliferative and proapoptotic effect. Tamoxifen, raloxifene, and toremifene have been found to inhibit the proliferation of both prostatic epithelial cells and prostatic stromal cells in vitro (Glienke et al., 2004; Nomura et al., 2009). Moreover, tamoxifen significantly reduced PV by 28.5% in a randomized trial in dogs (Gonzalez et al., 2009). Trials assessing the effect of SERMs for the treatment of BPH in humans are limited. Tamoxifen was tested in 10 patients before they underwent BPH surgery, showing a reduced level of nuclear androgen receptors on the analysis of prostate specimens after surgery (Albert et al., 1984). In a population of patients with metastatic PCa, the use of SERMs was shown to ameliorate AEs associated with antiandrogen therapy, thus reducing the risk for fracture and improving the lipid profile (Smith et al., 2008). For these reasons, SERMs may play a role in the future for the treatment of BPH as a potential adjuvant to antiandrogen therapies.

Selective androgen receptor modulators (SARMs) exert a tissue-selective effect; they act as partial antagonists on the prostate and as full agonists at the level of the muscle tissue and pituitary gland, thus inducing a suppression of prostate growth while maintaining a positive effect peripherally (Negro-Vilar, 1999). In vivo studies on rat models have shown a dose-dependent decrease in PV associated with SARM treatment, without significant changes in serum testosterone and gonadotropin hormone concentrations (Gao et al., 2004; Nejishima et al., 2012). Further trials are needed to test the effect of SARMs in patients with BPH.

Tolerability and Safety of Androgen Manipulation Therapy for Benign Prostatic Hyperplasia

Pooled analyses of RCTs have demonstrated an overall good safety profile of 5ARIs (Park et al., 2014; Tacklind et al., 2010). Apart from sexual side effects, finasteride showed no significant difference in the overall incidence of AEs or serious AEs when compared with placebo (Tacklind et al., 2010); similarly the rate of patients stopping therapy because of AEs was not higher in the finasteride group than in the placebo group (Tacklind et al., 2010). In the long-term PLESS, after 4 years of treatment the rate of patients withdrawing therapy for AEs was 34% in the finasteride group and 42% in the placebo group (McConnell et al., 1998). Similarly, pooled data from RCTs of dutasteride did not show a significant higher incidence of AEs other than sexual dysfunction after treatment with dutasteride or placebo (Park et al., 2014). The large 4-year randomized REDUCE trial showed no difference in terms of AE rates between dutasteride and placebo (Andriole et al., 2010). **However, data from more recent studies have raised questions regarding the safety of 5ARIs because of controversial findings on the risk for treatment-emergent insulin resistance and diabetes, cardiovascular disease, and depression.**

Preclinical data showed that the dual inhibition of 5α-reductases promoted by dutasteride was associated with impaired insulin sensitivity in peripheral tissues and with increased body fat in an animal model (Upreti et al., 2014). Similarly, other animal studies have suggested an increased risk for nonalcoholic fatty liver disease associated with 5ARI treatment (Livingstone et al., 2015). These data are in line with findings demonstrating an increased risk for type 2 diabetes mellitus in men with lower testosterone levels (Corona et al., 2006). **However, the association between diabetes and 5ARI therapy in patients with BPH has not been confirmed in clinical studies.** Data from the REDUCE trial did not show an increased risk for diabetes in the dutasteride treatment group (Wu et al., 2011). Similarly, in a population-based study including 1298 patients with diagnosed BPH, the use of 5ARIs was not associated with the occurrence of type 2 diabetes in a 5-year period (3.5% vs. 5.3% with 5ARIs vs. control group). Moreover, patients younger than 65 years of age treated with 5ARIs showed lower risk for developing diabetes compared with same-age controls (Lee et al., 2016). Similarly, long-term data from the PCPT did not show any difference in the cumulative incidence of diabetes among patients treated with finasteride versus placebo (Unger et al., 2016).

Given the important role of androgens in the metabolism of bone and muscle, treatment with 5ARIs, affecting the serum level of DHT, may have an influence at these two levels; a population-based study including 1352 men with osteoporosis compared with 5387 controls reported a 1.5-fold increase of osteoporosis diagnosis among patients treated with finasteride (Lin et al., 2015). However, these findings were not corroborated by data from RCTs; **the bone mineral density of patients receiving finasteride for 4 years was not significantly different as from that of patients receiving placebo** (Matsumoto et al., 2002)**. Similar results were reported with dutasteride** (Amory et al., 2008). Moreover, a recent randomized trial evaluating the effect of testosterone therapy in patients treated with dutasteride versus placebo showed no difference in the effect of testosterone on fat-free mass and muscle strength, suggesting that the suppression of DHT does not affect the anabolic effect of testosterone on muscle (Bhasin et al., 2012).

The link between low testosterone level and the risk for cardiovascular events has raised concerns regarding a possible association between 5ARIs and cardiovascular diseases. Andriole et al. (2010) reported a higher incidence of cardiac failure among patients treated with dutasteride versus placebo in the REDUCE trial. Conversely, long-term results of the PCPT did not show a higher cumulative incidence of cardiovascular events among patients treated with finasteride (Unger et al., 2016). **In a recent population-based study including 36,311 men treated with dutasteride and 36,311 men treated with finasteride, there was no difference in the risk for heart failure and acute myocardial infarction between the two groups** (Skeldon et al., 2017); these results were corroborated by a nation-based study comparing 1486 men treated with 5ARIs with 9995 controls, showing that the active treatment was not associated with an increased risk for cardiovascular disease (Hsieh et al., 2015).

In 2011, the FDA added depression as a potential side effect in the product monograph of 5ARIs because of postmarketing studies reporting a higher risk for depression and suicide associated with finasteride use. Data from PCPT reported a 10% higher risk for depression associated with finasteride compared with placebo (Unger et al., 2016). Similar findings were reported in a cross-sectional study investigating the link between depressive symptoms and 5ARIs (Pietrzyk et al., 2015). This association may be related to the role of testosterone and DHT in the modulation of neuroendocrine stress response and in the production of neuroactive steroids. A recent population-based study including 93,197 men showed that the use of 5ARIs was not associated with an increased risk for suicide, whereas there was a significantly higher risk for depression (HR, 1.94; 95% CI, 1.73 to 2.16) and self-harm for men treated with 5ARIs (Welk et al., 2017). **Patients should be properly counseled regarding the risk for depressive symptoms associated with 5ARI treatment.**

5α-Reductase Inhibitors and Sexual Dysfunction

Both finasteride and dutasteride have been associated with the risk for sexual side effects, including erectile dysfunction, decreased libido, and ejaculation disorders. The biologic reasons behind this association are not fully clarified; the decrease of serum DHT level has been associated with decreasing levels of nitric oxide and nitric oxide synthase in the corpus cavernosum (Pinsky et al., 2011). Moreover, structural changes at the level of the cavernosal tissue have been observed after therapy with 5ARIs (Oztekin et al., 2012). In a 2-year RCT, the erectile dysfunction rate among patients treated with finasteride was

15.8% compared with 6.3% for patients receiving placebo (Nickel et al., 1996). Data from the large PLESS showed a higher rate of patients reporting decreased libido and decreased ejaculate volume in the finasteride group as compared with the placebo group after 1 year of treatment (McConnell et al., 1998). Similarly, data from a placebo-controlled trial showed a 7.3% incidence of erectile dysfunction after dutasteride treatment, along with a 4.2% of patients complaining of decreased libido and 2.2% of patients complaining of ejaculation disorders (Roehrborn et al., 2002). Comparable data on dutasteride were also reported in the REDUCE trial (Andriole et al., 2010).

Two recently published meta-analyses reported pooled results of randomized trials assessing sexual side effects after treatment with 5ARIs (Corona et al., 2017; Liu et al., 2016). Liu et al. (2016) pooled data from nine studies investigating the safety of 5ARIs in patients with BPH. The authors reported a relative risk of 1.55 (95% CI, 1.48 to 4.42) for erectile dysfunction and 1.69 (95% CI, 1.03 to 2.79) for decreased libido for patients treated with 5ARIs compared with placebo; no differences were found when data from patients treated with finasteride or dutasteride were compared. These results were further confirmed in a second meta-analysis (Corona et al., 2017). Moreover, a pooled data analysis looking at ejaculation disorders associated with LUTS therapies confirmed a significantly higher risk for ejaculation disorders after 5ARI treatment than after placebo treatment (Gacci et al., 2014).

Controversial findings have been reported regarding the time of onset and duration of sexual dysfunction associated with 5ARI therapy. Long-term data from the PCPT showed that the effect of finasteride on sexual function decreased over time (Moinpour et al., 2007). Similarly, in PLESS the rate of reported sexual side effects was no longer significant after 2 to 4 years of treatment (Wessells et al., 2003). Conversely, data from a meta-analysis of randomized trials showed a higher risk for sexual dysfunction among patients treated with 5ARIs for more than 1 year as compared with those treated for less than 1 year (Liu et al., 2016). Similarly, preclinical studies have shown an incomplete restoration of erectile function after discontinuation of dutasteride treatment (Oztekin et al., 2012).

Therefore, patients should be properly counseled regarding the possibility of experiencing erectile dysfunction, decreased libido, or ejaculation disorders after therapy with 5ARIs.

Summary

Multicenter RCTs have demonstrated the efficacy of finasteride and dutasteride for the treatment of patients with BPH. Therapy with finasteride has been associated with a roughly 20% reduction of PV along with modest relief of urinary symptoms and modest improvement of urinary flow parameters as compared with placebo. Of note, long-term data have shown a 51% reduction in the risk for either AUR or surgery for patients treated with finasteride. Comparable results have been reported in RCTs assessing the efficacy of dutasteride versus placebo. Both finasteride and dutasteride have a higher efficacy in patients with larger PV; long-term (≥6 months) treatment is required to observe a significant reduction of PV and a benefit in terms of symptom relief.

Safety profile data of 5ARIs demonstrated a higher risk for sexual dysfunction and depressive symptoms associated with both finasteride and dutasteride, although the overall incidence of AEs is generally low. Currently, there are no solid data to support a higher risk for diabetes mellitus or cardiovascular diseases associated with 5ARIs.

In the REDUCE trial and PCPT, a reduction in PCa incidence was observed after therapy with 5ARIs. However, caused by a concomitant small increase in the detection of high-grade tumors, neither finasteride nor dutasteride are indicated for PCa prevention.

Antiandrogens have also been investigated for treatment of LUTS/BPH. Current studies failed to demonstrate clinically significant efficacy of these drugs in patients with LUTS. The equivocal efficacy and problematic toxicity of antiandrogens have limited the enthusiasm for marketing these drugs for the treatment of LUTS/BPH. The role of GnRH antagonists requires further assessment. International clinical guidelines suggest therapy with 5ARIs for patients with an enlarged prostate (>40 mL) and moderate to severe symptoms.

Muscarinic Receptor Antagonists

Muscarinic receptor antagonists are used for the treatment of patients with BOO presenting with predominant and/or bothering storage LUTS. From 11% to 16% of men in Europe and North America complain of storage symptoms (Irwin et al., 2006; Stewart et al., 2003), and a non-negligible portion of them may suffer from concomitant BOO. Antimuscarinics (or anticholinergic compounds) are considered the mainstay of treatment for patients with OAB; their use in selected patients with LUTS has increased in the past two decades.

Rationale and Indication for Patients With Benign Prostatic Hyperplasia

The detrusor muscle receives parasympathetic innervation from cholinergic fibers responsible for the stimulation of muscarinic receptors at the peripheral level. Muscarinic receptors are responsible for involuntary detrusor contractions and are involved in the determination of the sensory threshold of the bladder (Chess-Williams et al., 2001). Of the five muscarinic receptor subtypes (M_1 to M_5), M_2 and M_3 receptors are predominant at the bladder level; the inhibition of these receptors through antimuscarinic drugs reduces involuntary bladder contractions and alters the contraction threshold, thus resulting in decreased urgency and increased bladder capacity (Chapple et al., 2002). There is an increasing body of evidence showing that antimuscarinics act mainly on bladder sensory pathways rather than motor pathways (Andersson, 2011); moreover, their effect might also be induced or modulated through the bladder urothelium or by the CNS (Kono et al., 2006).

Muscarinic receptor antagonists are mainly used for the treatment of patients with OAB syndrome; however, both the European and the American international clinical guidelines support the use of these compounds to treat patients with BOO mainly presenting with storage LUTS (McVary et al., 2011; Oelke et al., 2013). Of note, antimuscarinic therapy should be carefully administered in this subset of patients, given the associated higher risk for urinary retention and the risk for an increased PVR volume.

The following muscarinic receptor antagonists are licensed for treatment of storage symptoms: darifenacin hydrobromide (darifenacin), fesoterodine fumarate (fesoterodine), oxybutynin hydrochloride (oxybutynin), propiverine hydrochloride (propiverine), solifenacin succinate (solifenacin), tolterodine tartrate (tolterodine), and trospium chloride. Table 145.12 reports recommended dose and administration for each compound.

TABLE 145.12

Antimuscarinic Drugs for the Treatment of Lower Urinary Tract Symptoms

DRUG	AVAILABLE FORMULATION	RECOMMENDED DAILY DOSE
Darifenacin ER	7.5-, 15-mg capsule	1 × day
Fesoterodine ER	4-, 8-mg capsule	1 × day
Oxybutynin ER	5-, 10-, 15-mg[b] capsule	1 × day (up to 20 mg/day)
Oxybutynin IR	2.5-, 5-mg[a] capsule	3-4 × day (max 20 mg/day)
Propiverine ER (no US)	30-mg capsule	1 × day
Propiverine (no US)	15-mg capsule	2–3 × day
Solifenacin	5-, 10-mg capsule	1 × day
Tolterodine IR	1-, 2-mg capsule	2 × day
Tolterodine ER	2-mg[b], 4-mg capsule	1 × day 1 × day
Trospium IR	20-mg capsule	2 × day
Trospium ER	60-mg capsule	1 × day

Efficacy

The efficacy of antimuscarinic monotherapy for storage symptoms in patients with BOO associated with BPH has been investigated in a few trials (Table 145.13). In a small open-label prospective study, Kaplan et al. (2005) reported data from 43 patients with symptomatic BPH who received α1-blocker therapy for at least 1 month without efficacy. All patients were treated with 4 mg tolterodine ER formulation daily for 6 months. There was a significant decrease of the 24-hour micturition frequency (from 9.8 to 6.3 voids) and of the nocturia episodes (from 4.1 to 2.9); moreover, overall symptoms were relieved significantly after 1 month of treatment, and there was a significant increase in

PFR and PVR volume. Of note, no episodes of AUR were reported. In the first large RCT assessing the effect of antimuscarinic therapy for patients with proven BOO, Abrams et al. (2006b) randomized men with evidence of BOO and DO on urodynamic tests to receive tolterodine at 2 mg twice daily versus placebo for 12 weeks. Patients with a PVR volume greater than 40% of the maximum cystometric capacity and a history of urinary retention during the preceding 12 months were excluded. **Treatment with tolterodine was associated with a significant reduction of BOOI compared with placebo; significant differences in terms of the volume to the first detrusor contraction (+59 mL; 95% CI, 19 to 100 mL) and in the maximum cystometric capacity (+67 mL; 95% CI, 35 to 103 mL) favoring tolterodine over placebo ($P < 0.003$) were also observed.** The authors reported a 25-mL mean significant PVR volume increase after tolterodine therapy; however, the overall AE rate was not significantly different compared with placebo, and only three episodes of urinary retention were recorded in the tolterodine group. Less enthusiastic results in terms of efficacy were reported in a larger trial of 879 men with OAB and BOO symptoms randomized to receive tolterodine ER formulation at 4 mg/day, tamsulosin at 0.4 mg/day, tolterodine in combination with tamsulosin, or placebo for a total of 12 weeks (Kaplan et al., 2006). As a primary end point, the authors looked at patients who perceived treatment benefit at the end of treatment; **patients treated with tolterodine as a monotherapy did not report any significant improvement in terms of measures of urgency or significant reduction of IPSS compared with patients who received placebo. Only one patient reported AUR in the tolterodine group, although it must be noted that men with PVR volume greater than 200 mL and PFR less than 5 mL/s were excluded from the study.** Conversely, in another small, randomized study, propiverine as a monotherapy was found to reduce frequency and urgency episodes in patients with BOO (Yokoyama et al., 2009).

TABLE 145.13

Randomized Trials Investigating Antimuscarinic Drugs in Patients With Benign Prostatic Hyperplasia

	DRUG	PATIENTS	LENGTH OF	SYMPTOMS

			TREATMENT	
Saito et al., 1999	Tamsulosin Tamsulosin + propiverine	*N* = 134 Patients with detrusor overactivity	4 weeks	Greater reduction in daytime (44.7% vs. 29.6%) and nighttime frequency (44.4% vs. 33.5%) with tamsulosin + propiverine vs. tamsulosin alone
Athanasopoulos et al., 2003	Tamsulosin 0.4 mg Tamsulosin + tolterodine 2 mg bid	*N* = 50 Patients with urodynamically proven BOO and detrusor instability	12 weeks	Statistically significant reduction in quality of life score from the baseline only in patients treated with tamsulosin + tolterodine ($P<0.0003$)
Lee et al., 2005	Doxazosin 4 mg Doxazosin 4 mg + propiverine 20 mg	*N* = 211 ≥50 years of age with OAB symptoms and urodynamically proven BOO (mean PVR <31 mL)	8 weeks	Change in daytime frequency: Doxazosin + Propiverine –1.9; (P = 0.004) Doxazosin: –0.9 Change in nocturia episodes: Doxazosin + propiverine:

				–0.7; (*P* = 0.1) Doxazosin: –0.6

				–1.4 Propiverine + naftopidil: -2.0

AUR, Acute urinary retention; *bid,* twice a day; *BOO,* bladder outlet obstruction; *BOOI,* bladder outlet obstruction index; *BPH,* benign prostatic hyperplasia; *ER,* extended release; *IPSS,* International Prostate Symptom Score; *NR,* not reported; *NS,* not significant; *OAB,* overactive bladder; *PFR,* peak flow rate; *PVR,* postvoid residual volume.

Novara et al. (2006) performed a meta-analysis of four RCTs investigating antimuscarinics in men with BPH. Their results showed that monotherapy was not associated with reduction in the total IPSS; no significant changes in PFR were observed (0.1 mL/s; 95% CI, 0.6 to 0.7 mL/s). The PVR volume increased by 11.6 mL (95% CI, 4.5 to 18.6 mL), although AUR rates were not significant. **Overall, the efficacy of antimuscarinics alone in patients with BOO/BPH is controversial, although storage symptom relief has been demonstrated.**

In a study aimed at identifying patients who may have greater benefit from treatment with antimuscarinic drugs, those with higher IPSS storage symptom subscores and higher PFR had a higher chance of therapeutic success (Liao et al., 2013). Similarly, in a post hoc analysis of an RCT, patients with a baseline PSA level below 1.3 ng/mL showed a significant reduction in IPSS storage scores, daytime frequency, and frequency-urgency sum with tolterodine alone compared with placebo (Roehrborn et al., 2006), suggesting a possible greater benefit of antimuscarinic monotherapy in patients with OAB symptoms and small PV.

Tolerability and Safety Profile

Muscarinic receptors are expressed in several tissues, including the brain, heart, gut, salivary glands, and tear ducts. For this reason, **the use of antimuscarinic drugs may lead to treatment-related side effects, including dry mouth (≤16%), constipation (≤4%), nasopharyngitis (≤3%), dizziness (≤5%), and CNS side effects (cognitive dysfunction or delirium)** (Oelke et al., 2013). Both receptor selectivity and the specific molecular structure, influencing the diffusion of the drug into the brain, are responsible for the different tolerability profiles among antimuscarinics.

Oxybutynin was the first compound marketed for the treatment of OAB, but there was poor adherence for the IR formulation, with early discontinuation in a large number of patients (Rovner and Wein, 2002). Tolterodine ER formulation showed better tolerability. In a large multicenter RCT, dry mouth was the only AE more significantly reported in the tolterodine group than in the placebo group (23% vs. 8%) (Van Kerrebroeck et al., 2001). Similarly, in a four-arm trial comparing tolterodine ER formulation versus tamsulosin monotherapy versus combination therapy versus placebo in patients with BPH, the most frequently reported AEs were dry mouth (7%) and constipation (6%) (Kaplan et al., 2006). Of note, the side effects of the combination therapy of antimuscarinics with α_1-blockers or 5ARIs are those expected with each individual drug (Athanasopoulos et al., 2011).

Both solifenacin and fesoterodine have shown a higher rate of reported dry mouth and constipation compared with tolterodine ER formulation (Novara et al., 2008).

The risk for CNS side effects is of particular concern for vulnerable patients such as elderly men and those with CNS disorders. Because of greater diffusion through the blood-brain barrier, oxybutynin has shown a higher risk for CNS impairment compared with the other compounds (Kay and Ebinger, 2008). **The use of antimuscarinics with CNS activity should be avoided in patients with cognitive impairment** (Athanasopoulos et al., 2011).

Data from trials assessing the safety of antimuscarinics in patients with BOO showed a minimal effect in terms of PVR volume increase; tolterodine alone showed a 5.2-mL mean PVR volume increase in patients with BOO (Kaplan et al., 2006); moreover, the incidence of AUR among patients treated with antimuscarinics was not significantly higher than that among patients who received placebo (Athanasopoulos et al., 2011). In line with these findings, a preclinical study has demonstrated that the effect of antimuscarinic drugs on detrusor muscle contractions is unlikely to aggravate voiding difficulties in the presence of BOO (Füllhase et al., 2010). **However, all trials assessing the safety of antimuscarinics to treat storage symptoms associated with BOO included men with a PVR volume below 200 mL. Therefore, this treatment should be considered safe for patients presenting with a low PVR volume.**

Summary

Muscarinic receptor antagonists are the mainstay of treatment for patients with OAB syndrome. Few trials have assessed the efficacy and safety of

antimuscarinic therapy in patients with BOO related to BPH and presenting with prevalent storage symptoms. The results showed that antimuscarinics can be safely administered in patients with low PVR volume and no history of AUR. However, controversial findings have been reported regarding the efficacy of monotherapy with an antimuscarinic drug in patients with BPH. A few studies showed a benefit in reducing storage symptoms in men with lower gland volume.

International clinical guidelines suggest the use of antimuscarinic therapy in patients with moderate to severe LUTS who mainly complain of bladder storage symptoms and present with a baseline PVR volume lower than 200 mL (McVary et al., 2011; Oelke et al., 2013).

β3-Agonist (Mirabegron)

The β_3 subtype is the predominant form of β-ARs in the bladder (Yamaguchi and Chapple, 2007); **the stimulation of the β_3-AR is responsible for an increase in bladder capacity without a significant change in micturition pressure, PVR volume, and voiding contraction** (Leon et al., 2008). Mirabegron is the first β_3-agonist internationally approved for the treatment of storage symptoms.

Indication, Efficacy, and Safety Profile

Mirabegron acts as a β_3-AR agonist at the level of the bladder, inducing detrusor smooth muscle relaxation and contributing to urine storage (Aizawa et al., 2012). Phase III randomized trials provided evidence of the efficacy of mirabegron for the treatment of patients with OAB syndrome (Chapple et al., 2013; Khullar et al., 2013). Few data are currently available regarding the safety and efficacy of mirabegron in the selected population of patients with BOO associated with BPH.

Nitti et al. (2013) conducted a phase II randomized trial aimed at evaluating urodynamic parameters in 200 men with LUTS and BOO treated with mirabegron at 50 or 100 mg daily versus placebo. At the end of the 12-week therapy, mean values of PFR and detrusor pressure at Qmax were not significantly different across groups; moreover, the number of patients for whom the BOOI score category shifted (from equivocal to obstructed) decreased in the treatment arms at the end of treatment. However, a dose-dependent increase in PVR volume of about 30 mL was observed in the 100-mg group. Patients treated with mirabegron showed a significant decrease in the mean number of micturitions per day (–1.37) and urgency episodes per day (–1.60) compared with patients who received placebo; conversely, no significant difference was observed in terms of changes of IPSS voiding and storage scores between the placebo group and the mirabegron-treated groups. **These results support the urodynamic safety of mirabegron in patients affected by BOO and suggest a role in the treatment of storage symptoms in this setting.** Recent evidence suggests that mirabegron might exert an effect also at the level of the urethra (Alexandre et al., 2016). Preclinical data showed that mirabegron was able to induce relaxation of the urethral smooth muscle in an animal model. This effect was mediated by binding to the β_3-AR at the urethral level and by a selective block of the α_{1a}-ARs and α_{1d}-ARs. A similar effect on the prostatic smooth muscle was also reported by another group (Calmasini et al., 2015).

Compared with antimuscarinics, mirabegron is expected to have a better tolerability profile; indeed, given the different receptor target of this drug, side effects such as constipation, dry mouth, and neurologic impairments are uncommonly observed with mirabegron. Similarly, the inhibition of the β_3-AR at the level of the bladder does not appear to be associated with impairment of the voiding phase (Nitti et al., 2013). In a recent review of data from three 12-week trials of mirabegron versus placebo and two noninferiority trials comparing mirabegron with solifenacin and tolterodine, Tubaro et al. (2017) analyzed the safety and tolerability of mirabegron. A total of 37% of patients included in these trials had a history of BPH. Overall, the rate of AEs was not significantly different compared with placebo treatment (46.1% vs. 45.2%); the rate of dry mouth was significantly higher for patients treated with solifenacin (6.7%) and tolterodine (8%) compared with mirabegron (3.3% to 3.5%), whereas no difference was observed for constipation. The most commonly reported AEs in the mirabegron group were nasopharyngitis (5.9% to 3.3%), headache (2.4% to 3.1%), and hypertension (10% to 12%), although the latter was reported at a comparable rate in patients in the placebo group. Similarly, pooled data from 12-week phase III trials showed that mirabegron was associated with only a ≤1 mm Hg increase in blood pressure as compared with placebo (Rosa et al., 2016). **However, because of previous evidence showing a significant increase of systolic blood pressure among healthy volunteers** (Malik et al., 2012)**, mirabegron is not recommended for patients with uncontrolled hypertension.** Only three cases of AUR were reported, and PVR volume did not significantly change compared with placebo treatment.

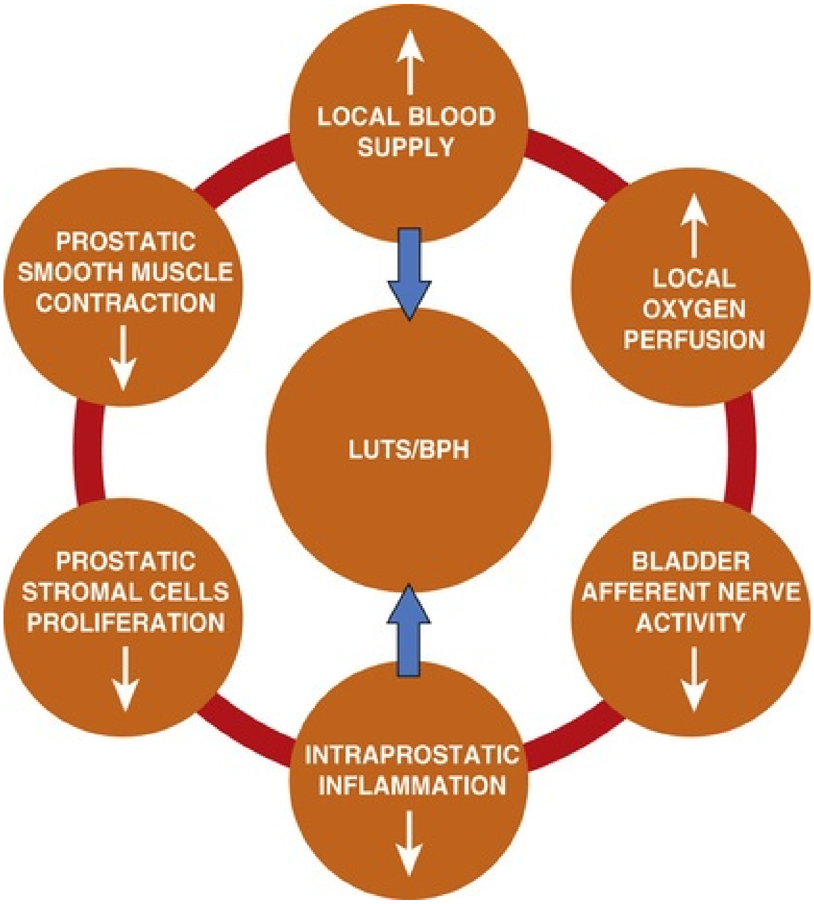
International clinical guidelines suggest the use of mirabegron as an option for the treatment of patients with moderate to severe LUTS and prevalent storage symptoms (Abrams et al., 2013; Oelke et al., 2013)**. The recommended starting dose is 25 mg daily with or without food, which may be further increased to 50 mg.**

Phosphodiesterase Type 5 Inhibitors

Erectile dysfunction and LUTS are strongly correlated (Gacci et al., 2011); PDE5Is demonstrated a beneficial effect in both conditions in several randomized trials (Gacci et al., 2012a). It has been proposed that PDE5Is may act by reducing inflammation and increasing oxygenation at the level of the prostatic tissue, thus normalizing the structural anatomy and physiologic activity of the prostate (Morelli et al., 2013; Vignozzi et al., 2013).

Rationale and Efficacy of Phosphodiesterase Type 5 Inhibitors in Patients With Lower Urinary Tract Symptoms

The enzyme PDE5 is expressed throughout the entire lower urinary tract (Fibbi et al., 2010). The biologic mechanisms associated with its inhibition have not been completely clarified, although there are several theories supporting a role for PDE5Is in the treatment of male LUTS (Fig. 145.12):



↑ LOCAL BLOOD SUPPLY
↑ LOCAL OXYGEN PERFUSION
BLADDER AFFERENT NERVE ACTIVITY ↓
INTRAPROSTATIC INFLAMMATION ↓
PROSTATIC STROMAL CELLS PROLIFERATION ↓
PROSTATIC SMOOTH MUSCLE CONTRACTION ↓
LUTS/BPH

FIG. 145.12 Effects of phosphodiesterase type 5 inhibitors on the lower urinary tract.

- **The inhibition of PDE5 at the level of the endothelial and smooth muscle cells of blood vessels can lead to increased oxygenation of both the bladder and the prostate** (Morelli et al., 2010). Both vardenafil and tadalafil were demonstrated to improve bladder and prostate oxygenation in a rat model (Morelli et al., 2009, 2011).
- **PDE5Is can relax the prostate and bladder neck smooth muscle** (Angulo et al., 2012; Kedia et al., 2009). This effect is associated with an increase in nitric oxide signaling from nerve fibers close to the muscle fibers. In rat models of partial urethral obstruction, the administration of vardenafil and tadalafil improved the urodynamic profile (Kawai et al., 2016; Morelli et al., 2009).
- PDE5 is greatly expressed at the level of prostatic stroma; **in human prostatic tissue preparations, vardenafil showed an antiproliferative effect** mediated by the cyclic GMP/protein kinase G pathway (Fibbi et al., 2010; Morelli et al., 2009). Moreover, PDE5Is inhibited fibroblast-myofibroblast transdifferentiation in human prostatic cells (Zenzmaier et al., 2010) and reversed stromal remodeling (Zenzmaier et al., 2012).
- **In rat models, PDE5Is decreased the activity of afferent nerves in the lower urinary tract, with a hypothesized consequent decrease in terms of perception of bladder filling and urgency** (Caremel et al., 2010). This effect is mediated by the nitric oxide/cyclic GMP pathway, and vardenafil resulted in significant improvement in urodynamic parameters in patients with neurogenic bladder secondary to spinal cord injury (Gacci et al., 2007).
- Metabolic syndrome has a proven role in BPH pathophysiology; in a rabbit model with metabolic syndrome–associated prostate alterations, tadalafil was able to **reduce prostate inflammation** (Morelli et al., 2013)**, suggesting that PDE5Is may attenuate the negative effect of metabolic alterations on prostatic tissue.**

The effects of PDE5I therapy in patients with LUTS have been evaluated in several RCTs (Table 145.14) and in trials comparing α_1-blockers with PDE5Is; moreover, several meta-analyses provided further evidence regarding the use of PDE5Is in the treatment of LUTS (see Table 145.14). The first evidence of a PDE5I-associated relief of LUTS came from a study including 112 men treated with sildenafil for erectile dysfunction (Sairam et al., 2002); IPSS data showed an unexpected relief of symptoms with sildenafil treatment.
